Brief Summary of Prescribing Information

ADAPIN® (doxepin HCl) Capsules

Indications—Relief of symptoms of anxiety and depression.

Contraindications—Glaucoma, tendency toward urinary retention, or hypersensitivity to doxepin.

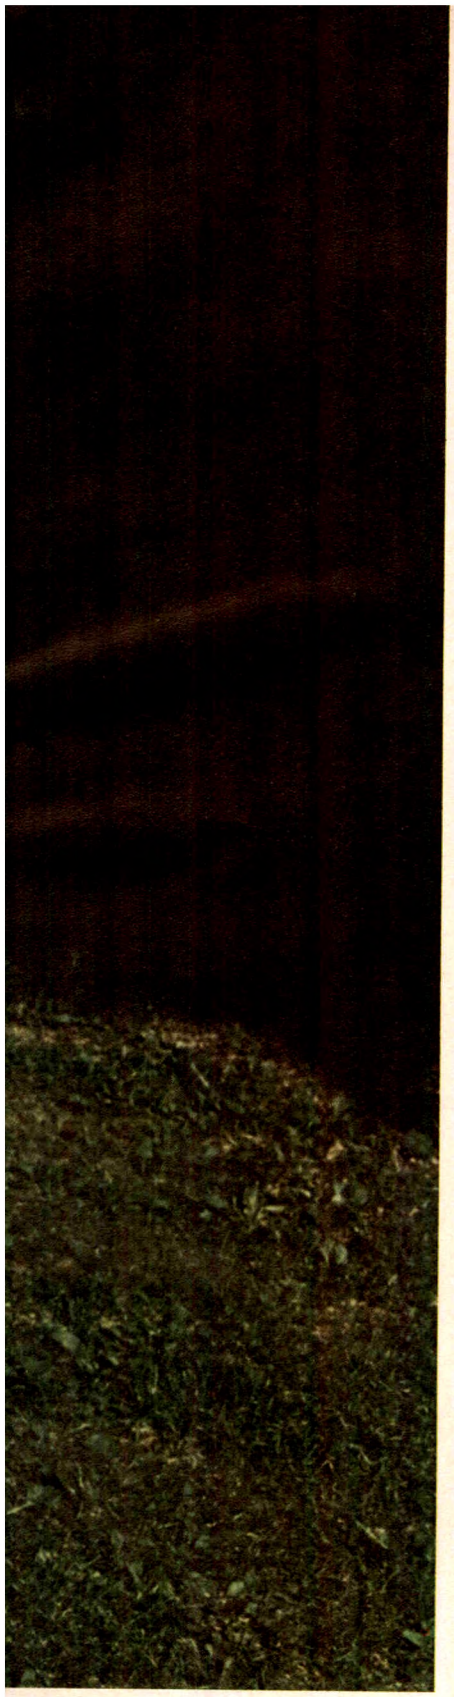
Warnings—Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions—Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Adverse Reactions—Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.



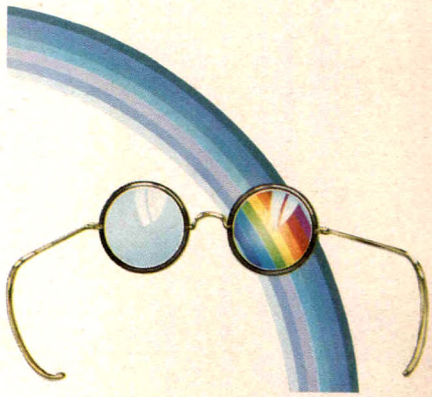
Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may als occur.

Dosage and Administration—In mild to moderate anxiety and/ depression: 25 mg t.i.d. Increase or decrease the dosage accordi to individual response. Daily dosage, up to 150 mg may be taken bedtime without loss of effectiveness. Usual optimum daily dosa is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect two or three weeks.

How Supplied—Each capsule contains doxepin, as the h drochloride: **10 mg, 25 mg, 50 mg, and 100 mg** capsules in bottl of 100 and 1000.

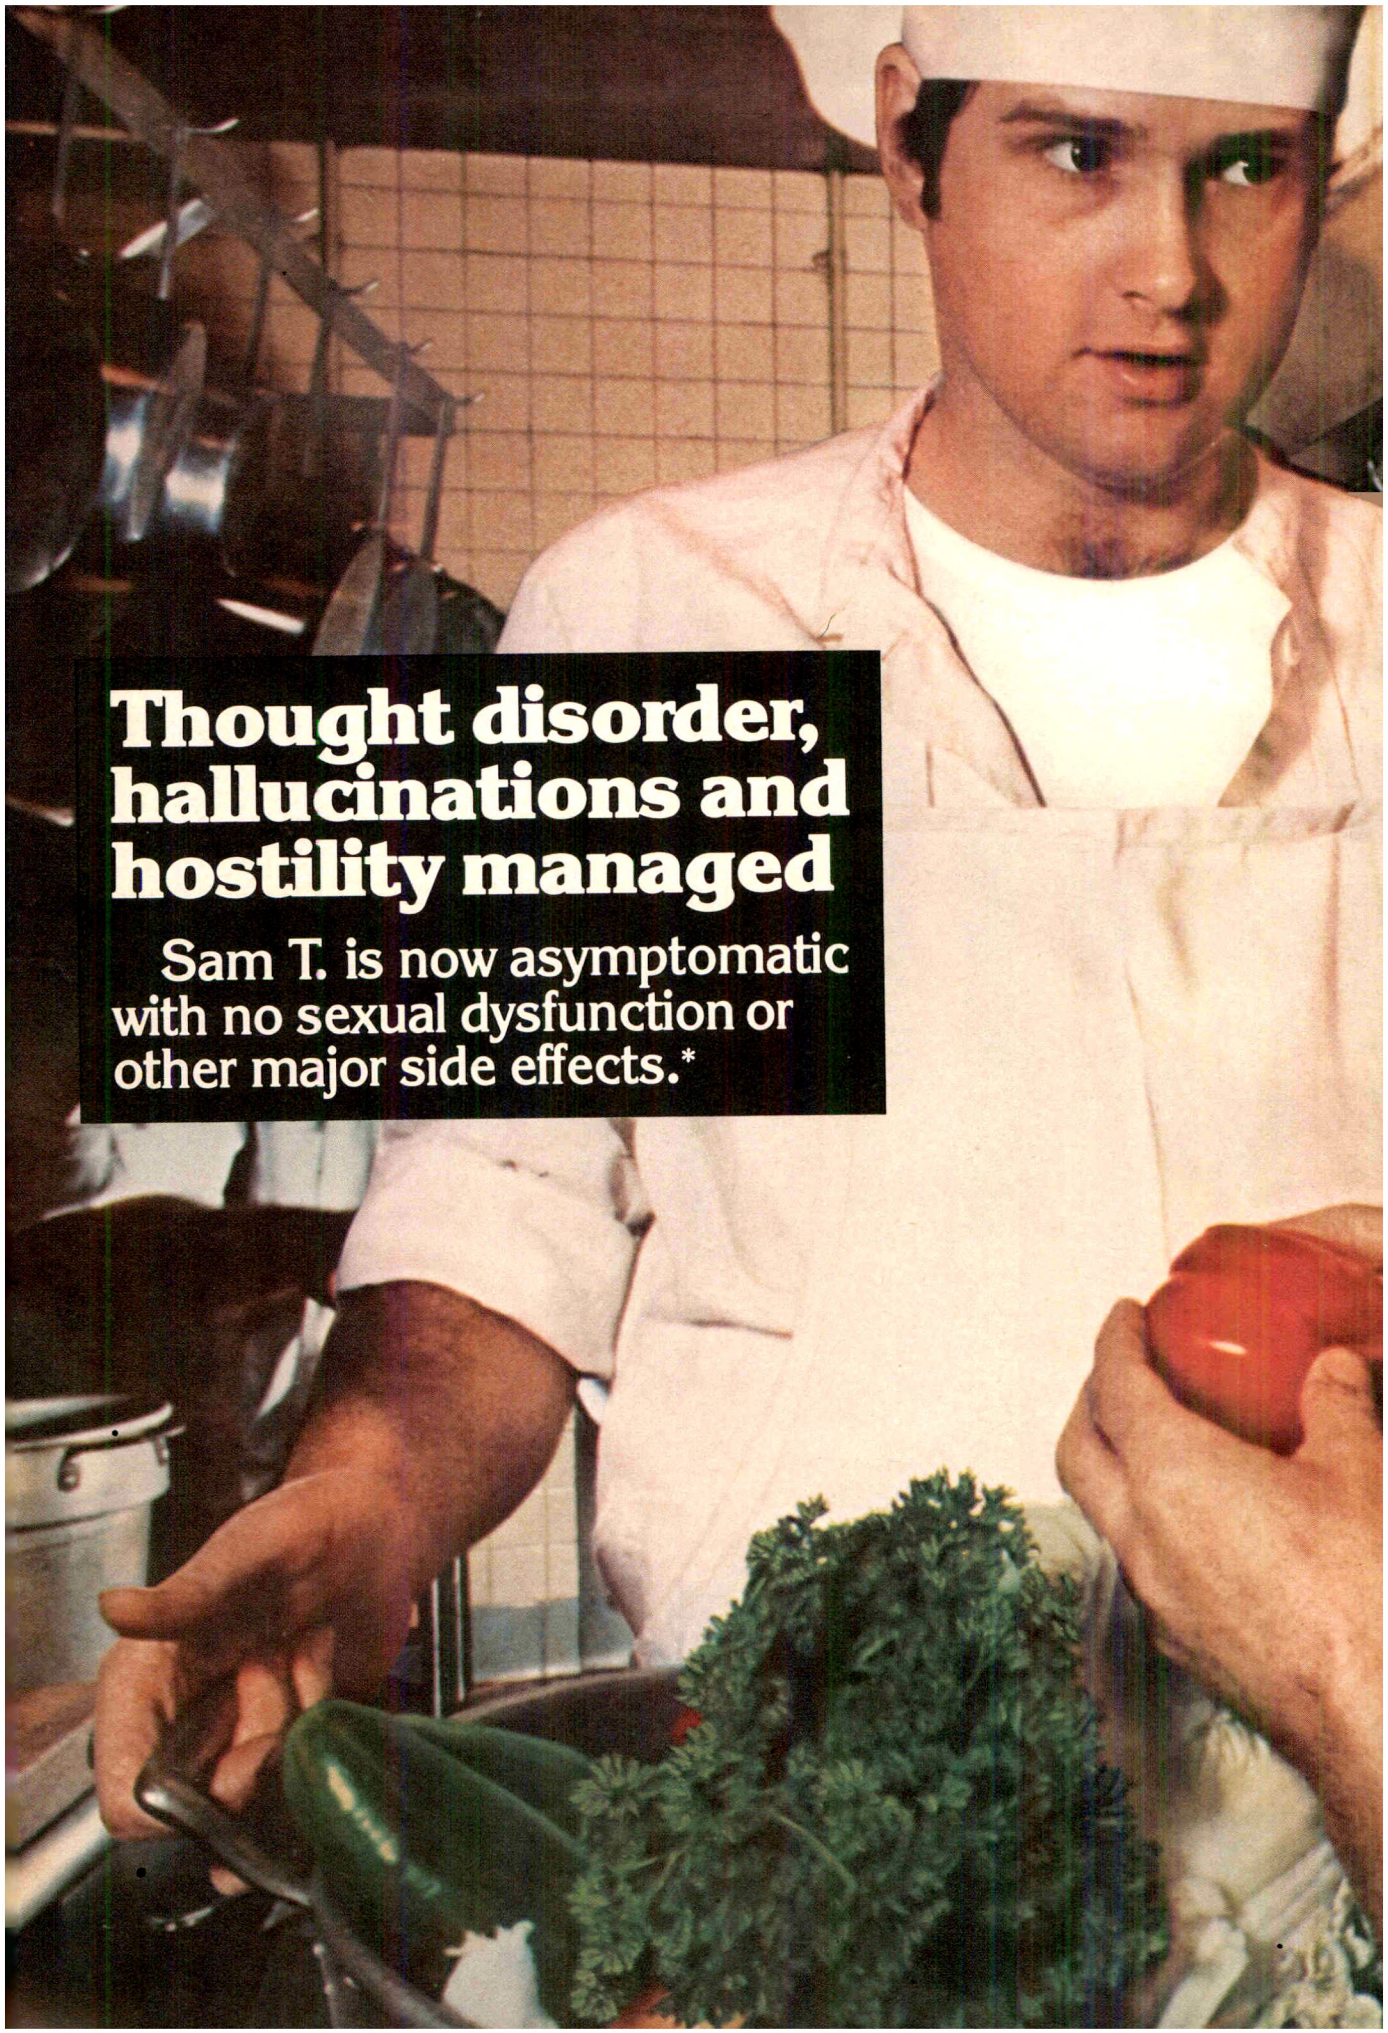
For complete prescribing information please see package inse or PDR.



in anxiety/depression...

a good awakening from a good night's sleep

Most depressed patients experience some form of sleep disturbance. Adapin® helps relieve the accompanying anxiety, and restores a more normal sleep pattern right from the start of therapy.



☐ **convenient, flexible therapy**
The usual optimal dose is 75 to 150 mg daily. The entire dose may be given at night without loss of therapeutic effect. Adapin is available as 10 mg, 25 mg, 50 mg, and 100 mg capsules.

Thought disorder, hallucinations and hostility managed
Sam T. is now asymptomatic with no sexual dysfunction or other major side effects.*

LOXITANE® Loxapine Succinate

Permits rapid management of Sam's hostility and excited behavior

Thirty-six year old salad maker, claiming to be the "Wild Man of the West" was brought to the hospital by his kitchen supervisor. History revealed prior psychiatric hospitalizations and therapies including psychotropic drugs. Hypertension was noted as a complication of earlier treatment with anti-psychotic drugs. Diagnosis: chronic schizophrenia, acute exacerbation. He responded promptly to LOXITANE® C Loxapine HCl Concentrate 50 mg stat, followed by LOXITANE® Loxapine Succinate capsules 30 mg t.i.d.

Permits aggressive titration for rapid establishment of optimal management of Sam's thought disorder and hallucinations

During first week, LOXITANE dosage increased to 50 mg q.i.d. Significant improvement in thought disorder noted by third week. Auditory hallucinations and delusions much less frequent. Patient calmer and more cooperative.

Permits sustained symptom management with minimal risk of serious adverse effects, such as sexual dysfunction

Patient revealed that while on outpatient status, he failed to take his previously prescribed antipsychotic for a ten-month period after he met and married his girlfriend. He stated the drug "didn't let me be a man." No sexual dysfunction reported with LOXITANE.

Side effects are usually mild, transitory and easily managed

Patient felt anxious because his "heart was beating so fast," and he "could not sit still." Increased pulse rate and restlessness subsided following decrease of LOXITANE to 20 mg q.i.d.

Consistence in schizophrenic symptom management and tolerance promotes patient compliance

All admitting symptomatology under control by the fourth week. By the sixth week, he was anxious to return home. Stated "this medicine doesn't make me feel drowsy like the other did." Discharged by the eighth week. He returned to work fully managed on LOXITANE 20 mg t.i.d., and free from recurrence of previously reported side effects.

*Painful ejaculation and urine containing sperm have not been reported. Endocrine disturbances such as galactorrhea and menstrual irregularities have only been rarely reported. Other sexual side effects infrequently reported. Although not reported to date, possibility of hepatic, renal, ocular, or phototoxicity cannot be ruled out at this time. Transient liver enzyme changes not definitely related to LOXITANE have been reported. Not an actual patient, but a simulation to illustrate the action of LOXITANE as reported in clinical studies.

See LOXITANE prescribing information on following page for indications, warnings and precautions and for more detailed information concerning side effects.

Recommended Daily Dosage

	MILD	MODERATE	SEVERE
Initial Dosage	10 mg b.i.d.	10 mg t.i.d or q.i.d.	25 mg b.i.d.
First 7 to 10 days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Brief Summary
LOXITANE® Loxapine Succinate Capsules
LOXITANE® C Loxapine Hydrochloride Oral Concentrate
INDICATIONS: Manifestations of schizophrenia.
CONTRAINDICATIONS: Comatose or severely depressed states; hypersensitivity to the drug.
WARNINGS: Safe use during pregnancy or lactation has not been established; weigh potential benefits to possible hazards. Not recommended for use in children under 16. May impair mental and/or physical abilities especially during early therapy; warn ambulatory patients about activities requiring alertness and concomitant use of alcohol or other CNS depressants. Not recommended for management of behavioral complications in mentally retarded patients.
PRECAUTIONS: Use with extreme caution in patients with a history of convulsive disorders; use with caution in patients with cardiovascular disease or in those with glaucoma or a tendency to urinary retention particularly when on concomitant anticholinergic medication. Loxapine has an antiemetic effect in animals which might occur in man masking signs of overdosage of toxic drugs and obscuring intestinal obstruction or brain tumor. Since possible ocular toxicity cannot be excluded, observe carefully for pigmentary retinopathy and lenticular pigmentation.
ADVERSE REACTIONS: CNS effects, other than extrapyramidal, infrequent. Mild drowsiness may occur at beginning of therapy or upon dosage increase, usually subsides with continued therapy. Sedation, dizziness, faintness, staggering gait, muscle twitching, weakness and confusional states have been reported. Extrapyramidal reactions often occur early in treatment manifested by Parkinson-like symptoms (tremor, rigidity, excessive salivation, masked facies, akathisia) controllable by dosage reduction or antiparkinson drugs at usual dosages. Dystonic and dyskinetic reactions, while less frequently occurring, may be more severe, requiring dosage reduction or temporary withdrawal plus appropriate counteractive drugs. Persistent Tardive Dyskinesia may appear during prolonged therapy or following discontinuance, the risk greater in the elderly, especially females, on high dosage. Symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of the tongue, face, mouth and jaw sometimes accompanied by involuntary movement of extremities. Since there is no known effective treatment, discontinue all antipsychotic drugs if symptoms appear. Reinstitution of treatment, increased dosage, or switching to another agent may mask syndrome. The syndrome may not develop if medication is stopped when fine vermicular movements of the tongue first appear. Cardiovascular Effects: Tachycardia, hypotension, hypertension, lightheadedness and syncope. ECG changes, not known to be related to loxapine use, have been reported. Skin: Dermatitis, edema of face, pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of unknown etiology seen in a few patients in hot summer months. Anticholinergic: Dry mouth, nasal congestion, constipation, blurred vision (more likely to occur with concomitant use of antiparkinson agents). Other: Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of unknown etiology.

The easiest wa multiply and divid

Adds better dosage control

(+) Long term treatment of depression with amitriptyline requires careful dosage titration to meet the individual needs of each patient. Because all six strengths of Endep (amitriptyline HCl) are scored, you can easily change the dose by half-tablet steps, without waiting for the patient to fill a new prescription.

o add, subtract, mitriptyline...

Subtracts some of the drawbacks of antidepressant therapy

Scored Endep (amitriptyline HCl) tablets may eliminate the need for a new prescription each time the dosage needs to be changed, aving time for you and money for your patient. And, by keeping the atient on the same strength tablet, there's less chance he'll become onfused, as he might if changed to another size or color of mitriptyline.

Multiplies therapeutic options

The pharmacokinetic properties of Endep (amitriptyline HCl) are such that its clinical effect is the same whether prescribed *i.d.* or as a single daily dose. Thus, once you have established the roper dosage, you can prescribe the entire dose *h.s.*, minimizing nticholinergic and sedative side effects and helping to assure patient ompliance with this simple regimen.

By prescribing the higher strength tablets *h.s.*—secure in the nowledge that the dosage can be adjusted in half-tablet steps without sorting to a new prescription—your patient will economize further n a per milligram basis.

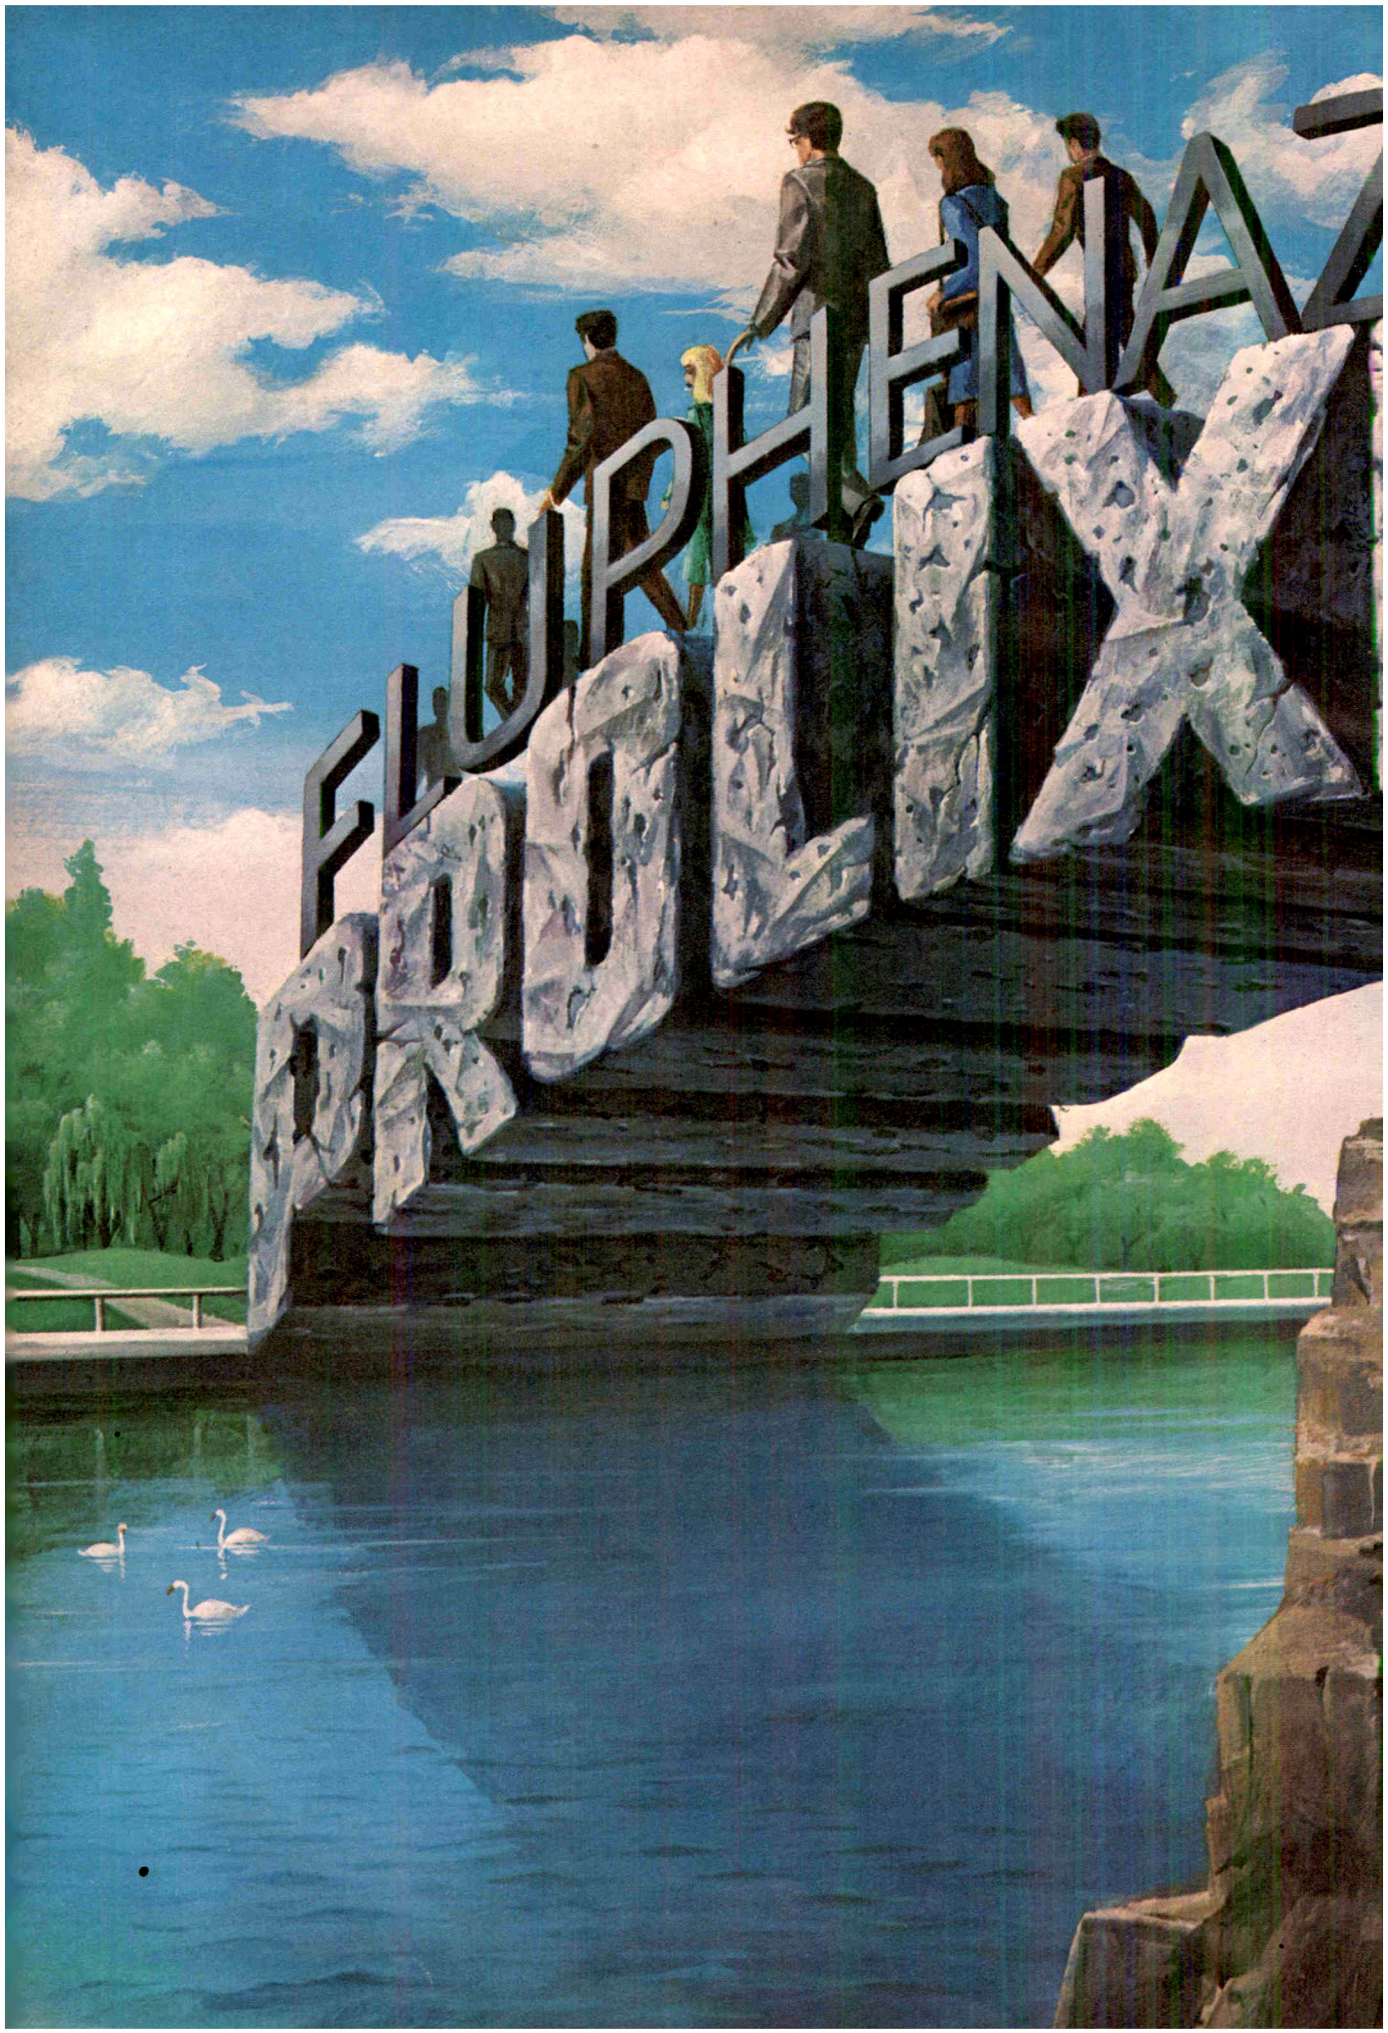
Endep®
amitriptyline HCl/Roche
The only amitriptyline scored for easy division

Endep
amitriptyline HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.



Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Supplied: *Scored Tablets:* 10, 25, 50, 75, 100, 150 mg.

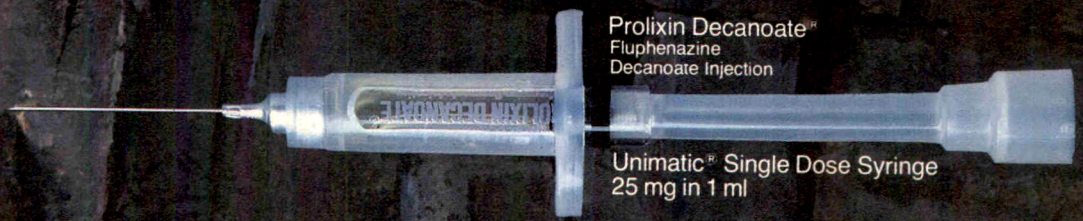
FLUR HENAZ
FROLIX

The Prolixin® (Fluphenazine) system of schizophrenia management—

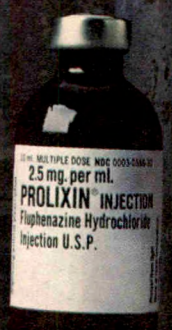
spanning virtually every clinical situation



There is scarcely a patient-type presenting with schizophrenia that cannot be successfully managed with one of the numerous forms of Prolixin (Fluphenazine).

For the newly admitted, agitated patient, a first choice would be short-acting Prolixin Injection (Fluphenazine Hydrochloride Injection USP).

For long-term management of more "dependable" patients, you have the titration flexibility of four potencies of Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP).



For patients who "cheek" or otherwise resist tablet medication, you can utilize pleasant tasting, orange-flavored Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP).

For long-term maintenance of less compliant patients, you can employ unique, long-acting Prolixin Decanoate (Fluphenazine Decanoate Injection) and achieve effective neuroleptization for up to four weeks and longer with a single injection.

See next page for brief summaries.

PROLIXIN® (Fluphenazine Hydrochloride)
TABLETS/ELIXIR/INJECTION

Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP) provide 1, 2.5, 5, or 10 mg fluphenazine hydrochloride per tablet. Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP) provides 0.5 mg fluphenazine hydrochloride per ml (2.5 mg per 5 ml teaspoonful) with 14% alcohol by volume. Prolixin Injection (Fluphenazine Hydrochloride Injection USP) provides 2.5 mg fluphenazine hydrochloride per ml; it contains 0.1% methylparaben and 0.01% propylparaben as preservatives.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine hydrochloride and other antipsychotic drugs is not known.

Periodic checking of hepatic and renal functions and blood picture should be done. Monitor renal function of patients on long-term therapy; if BUN becomes abnormal, discontinue fluphenazine. "Silent pneumonias" are possible.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence. However, gastritis, nausea and vomiting, dizziness, and tremulousness have been reported following abrupt cessation of high dose therapy; reports suggest that these symptoms can be reduced if concomitant antiparkinsonian agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. The incidence and severity of such reactions will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an anti-parkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines.

For full prescribing information, consult package inserts.

HOW SUPPLIED: *Tablets*—1 mg in bottles of 50 and 500; 2.5 mg and 5 mg in bottles of 50 and 500 and in Unimatic® single-dose cartons of 100; 10 mg in bottles of 50 and 500. *Elixir*—in bottles of 473 ml (1 pint) and in 60 ml dropper-assembly bottles with dropper calibrated at 0.5 ml (0.25 mg), 1 ml (0.5 mg), 1.5 ml (0.75 mg), and 2 ml (1 mg). *Injection*—in multiple-dose vials of 10 ml.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg fluphenazine dec per ml in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain dam patients who have a blood dyscrasia or liver damage, or who are receiving large dc hypnotics, or who are comatose or severely depressed. In patients who have shown hyp sitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating hea chinery may be impaired by use of this drug. Physicians should be alert to the possibil severe adverse reactions may occur which require immediate medical attention. Potentia effects of alcohol may occur. Safety and efficacy in children have not been established b of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; possible hazards against potential benefits if administering this drug to pregnant patie

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused tatic jaundice, dermatoses or other allergic reactions because of the possibility of sensitivity. When psychotic patients on large doses of a phenothiazine drug are to u surgery, hypotensive phenomena should be watched for; less anesthetics or central n system depressants may be required. Because of added anticholinergic effects, fluphe may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phos insecticides; in patients with a history of convulsive disorders since grand mal convulsio occurred; and in patients with special medical disorders such as mitral insufficiency cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal de and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician enced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal fu and blood picture should be done. Renal function of patients on long-term therapy sh monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneu are possible.

There is sufficient experimental evidence to conclude that chronic administration of chotic drugs which increase prolactin secretion has the potential to induce mammary nec in rodents under the appropriate conditions. There are recognized differences in the ph ical role of prolactin between rodents and humans. Since there are, at present, no ac epidemiological studies, the relevance to human mammary cancer risk from prolonged e to fluphenazine decanoate and other antipsychotic drugs is not known.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are m quently reported. Most often these symptoms are reversible, but they may be persister include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisth hyperreflexia. Muscle rigidity sometimes accompanied by hyperthermia has been following use of fluphenazine decanoate. One can expect a higher incidence of such re with fluphenazine decanoate than with less potent piperazine derivatives or straig phenothiazines. The incidence and severity will depend more on individual patient sensit dosage level and patient age are also determinants. As these reactions may be alarm patient should be forewarned and reassured. These reactions can usually be contr administration of an antiparkinsonian drug such as benztropine mesylate and by sub reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sor irreversible tardive dyskinesia may appear in some patients on long-term therapy or ma after discontinuation of drug. The risk seems greater in elderly patients, especially fem high dosages. The syndrome is characterized by rhythmical involuntary movements of face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, movements) and may be accompanied by involuntary movements of extremities. The known effective therapy for tardive dyskinesia; usually the symptoms are not allevi antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic a suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage inc or a different antipsychotic agent used. Reports are that fine vermicular movements of the may be an early sign of the syndrome which may not develop if medication is stopped at t

Phenothiazine derivatives have been known to cause restlessness, excitement, o dreams; reactivation or aggravation of psychotic processes may be encountered. If dro or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the mended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure ha reported. Although hypotension is rarely a problem, patients with pheochromocytoma, vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insu appear to be particularly prone to this reaction and should be observed carefully. Su measures including intravenous vasopressor drugs should be instituted immediatel severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epi should not be used* since phenothiazine derivatives have been found to reverse it Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and c tion may occur. Reducing or temporarily discontinuing the dosage will usually cont effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tach or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal la gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in increased libido in women have occurred in some patients on phenothiazine therap

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, ecze exfoliative dermatitis have been reported with phenothiazines. The possibility of anapl reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocyt nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been obser phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper re infection occur and confirmatory leukocyte count indicates cellular depression, therap be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during months of therapy, may occur; treatment should be discontinued. A cephalin floccu crease, sometimes accompanied by alterations in other liver function tests, has been re patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenot Previous brain damage or seizures may be predisposing factors. High doses should be in known seizure patients. Shortly before death, several patients showed flare-ups of p behavior patterns. Autopsy findings have usually revealed acute fulminating pneu pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not feature of fluphenazine, potentiation of central nervous system depressants such as analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to ca cardiac arrest, altered electrocardiographic and electroencephalographic tracings cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angi edema; with long-term use, skin pigmentation and lenticular and corneal opacities have with phenothiazines. Local tissue reactions occur only rarely with injections of flup decanoate.

SQUIBB® 'The Priceless Ingredient of every product is the honor and integrity of its maker.'™ •

ny patients,

HE RIGHT ANTIDEPRESSANT

No tricyclic antidepressant works more effectively to brighten the mood, relieve sleep disturbances, and ameliorate mild anxiety.[1,2] And none appears to be better balanced[3] in terms of the biogenic amine theory of depression, which relates depression to functional deficiencies of the catecholamines.

For Tofranil-PM is almost equally effective in inhibiting the postsynaptic uptake of both norepinephrine and serotonin, the two neurotransmitters most often implicated in depression, while other tricyclic antidepressants tested are heavily skewed towards one or the other.*

*Nortriptyline, a chemical derivative of amitriptyline, also exhibits balanced action, but does not appear as effective in treating serotonin-mediated depression as imipramine.

Please see last page for a brief summary of the prescribing information.

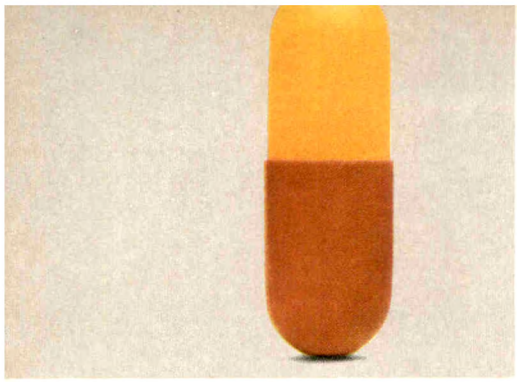
COMBINATION*...

Although Tofranil-PM provides a sedative effect, when you decide to add a tranquilizer for more control of the anxiety, you can confidently prescribe diazepam with Tofranil-PM.



Tofranil-PM is effective when used alone or with virtually any benzodiazepine selected—a flexibility difficult to achieve with fixed-combination antidepressant regimens.

The decision of which drugs to combine, and at what dosages, remains entirely in your hands . . . where it belongs.

* The actions of benzodiazepines may be potentiated by concomitant use with Tofranil-PM. Careful consideration should be given to the pharmacology of the agents in any such combination before prescribing.

Please see last page for a brief summary of the prescribing information.

for many patients, the right antidepressant, alone... or the basis of the right combination

Tofranil-PM® imipramine pamoate ...unsurpassed antidepressant action

For the majority of patients with neurotic depression, Tofranil-PM may be the only drug needed to produce a satisfactory brightening of mood.[1, 2] A recent report[4] notes that the two leading single-entity tricyclic antidepressants—imipramine pamoate (Tofranil-PM) and amitriptyline—provide equally effective antidepressant activity.

Better quality sleep—usually without morning "hangover"

Recent evaluation confirms that "...patients treated with imipramine pamoate tended ($P < .09$) to have a better quality of sleep than those treated with amitriptyline."[4]

75 mg 100 mg 125 mg 150 mg

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Many patients show good results on Tofranil-PM 75 mg h.s.; however, the most effective daily dose may be the 150-mg capsule.

Brief Summary of Prescribing Information

Indications For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states. One to three weeks of treatment may be needed before optimal therapeutic effects are evident.

Contraindications The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.

The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings Extreme caution should be used when this drug is given to:

—patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, congestive heart failure, myocardial infarction, strokes and tachycardia. These patients require cardiac surveillance at all dosage levels of the drug;
—patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
—hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
—patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
—patients receiving guanethidine, clonidine, or similar agents, since imipramine pamoate may block the pharmacologic effects of these drugs;
—patients receiving methylphenidate hydrochloride. Since methylphenidate hydrochloride may inhibit the metabolism of imipramine pamoate, downward dosage adjustment of imipramine pamoate may be required when given concomitantly with methylphenidate hydrochloride.

Since imipramine pamoate may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.

Tofranil-PM may enhance the CNS depressant effects of alcohol. Therefore, it should be borne in mind that the dangers inherent in a suicide attempt or accidental overdosage with the drug may be increased for the patient who uses excessive amounts of alcohol. (See **Precautions**.)

Usage in Children: Tofranil-PM should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg, 100 mg, 125 mg and 150 mg). Each capsule contains imipramine pamoate equivalent to 75 mg, 100 mg, 125 mg or 150 mg imipramine hydrochloride.

Precautions An ECG recording should be taken prior to the initiation of larger-than-usual doses of imipramine pamoate and at appropriate intervals thereafter until steady state is achieved. (Patients with any evidence of cardiovascular disease require cardiac surveillance at all dosage levels of the drug. See **Warnings**.) Elderly patients and patients with cardiac disease or a prior history of cardiac disease are at special risk of developing the cardiac abnormalities associated with the use of imipramine pamoate. It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with imipramine pamoate and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, imipramine pamoate may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes. An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine. Concurrent administration of imipramine pamoate with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Usage During Pregnancy and Lactation:
Animal reproduction studies have yielded inconclusive results.

There have been no well-controlled studies conducted with pregnant women to determine the effect of imipramine on the fetus. However, there have been clinical reports of congenital malformations associated with the use of the drug. Although a causal relationship these effects and the drug could not be establi possibility of fetal risk from the maternal ingest imipramine cannot be excluded. Therefore, im should be used in women who are or might be pregnant only if the clinical condition clearly ju potential risk to the fetus.

Limited data suggest that imipramine is likely t creted in human breast milk. As a general rule, woman taking a drug should not nurse since th possibility exists that the drug may be excrete breast milk and be harmful to the child.

Patients should be warned that imipramine pa may enhance the CNS depressant effects of a (See **Warnings.**)

Imipramine pamoate should be used with caut patients with significantly impaired renal or hep function.

Patients who develop a fever and a sore throat therapy with imipramine pamoate should have cyte and differential blood counts performed. I ramine pamoate should be discontinued if ther dence of pathological neutrophil depression.

Prior to elective surgery, imipramine pamoate s be discontinued for as long as the clinical situa allow.

In occasional susceptible patients or in those r anticholinergic drugs (including antiparkinson agents) in addition, the atropine-like effects ma come more pronounced (e.g., paralytic ileus). supervision and careful adjustment of dosage quired when imipramine pamoate is administe comitantly with anticholinergic drugs.

Avoid the use of preparations, such as decong and local anesthetics, which contain any symp mimetic amine (e.g., epinephrine, norepinephr since it has been reported that tricyclic antidep can potentiate the effects of catecholamines.

Caution should be exercised when imipramine oate is used with agents that lower blood pres Imipramine pamoate may potentiate the effect depressant drugs.

Patients taking imipramine pamoate should av cessive exposure to sunlight since there have l ports of photosensitization.

Both elevation and lowering of blood sugar lev been reported with imipramine pamoate use.

Adverse Reactions Note: Although the listing follows includes a few adverse reactions which not been reported with this specific drug, the p macological similarities among the tricyclic ant sant drugs require that each of the reactions b ered when imipramine is administered.

Cardiovascular: Orthostatic hypotension, hype tachycardia, palpitation, myocardial infarction, mias, heart block, ECG changes, precipitation gestive heart failure, stroke.

Psychiatric: Confusional states (especially in th derly) with hallucinations, disorientation, delusi iety, restlessness, agitation; insomnia and nigh hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesia tremities; incoordination, ataxia, tremors; perip neuropathy; extrapyramidal symptoms; seizure tions in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associa lingual adenitis; blurred vision, disturbances of commodation, mydriasis; constipation, paralyt urinary retention, delayed micturition, dilation c nary tract.

Allergic: Skin rash, petechiae, urticaria, itching sensitization; edema (general or of face and tc drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression includi agranulocytosis; eosinophilia; purpura; thromb penia.

Gastrointestinal: Nausea and vomiting, anorex epigastric distress, diarrhea; peculiar taste, sti abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast e ment and galactorrhea in the female; increase creased libido, impotence; testicular swelling; or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); alter function; weight gain or loss; perspiration; flusi nary frequency; drowsiness, dizziness, weakn fatigue; headache; parotid swelling; alopecia; ness to falling.

Withdrawal Symptoms: Though not indicative tion, abrupt cessation of treatment after prolon therapy may produce nausea, headache and

BRIDGING THE GAP FROM HOSPITAL TO COMMUNITY

SKILL TRAINING FOR COMMUNITY LIVING

A Comprehensive, Multimedia Program Using Structured Learning Therapy

By ARNOLD P. GOLDSTEIN, Syracuse University, and ROBERT P. SPRAFKIN and N. JANE GERSHAW, Syracuse VA Hospital and SUNY Upstate Medical Center

Published by Pergamon Press with Structured Learning Associates

What is Structured Learning Therapy (SLT)?
SLT is a behaviorally-oriented, psycho-educational approach to teaching patients the various interpersonal and planning skills necessary for them to function independently in the community.

What Skills Are Taught to Patients?
Using a series of audio tapes, Basic Skills such as interpersonal, conversational, and planning skills are taught first. After mastering these skills, the patient is exposed to Application Skills, which are combinations of Basic Skills designed to solve the more complex problems of daily living.

What Does the Complete Program Include?

Basic Skill Program
Consists of Basic Skill Tapes, 10 sets of pocket sized Skill Cards, and 10 Trainees' Notebooks designed to aid skill acquisition, 0 08 021469 X.....$270.00

Application Skill Program
Includes the Application Skill Tapes,
0 08 021112 7.....$147.00

Trainer Instruction Program
Consists of 2 texts: SKILL TRAINING FOR COMMUNITY LIVING: Applying Structured Learning Therapy and a brief, step-by-step TRAINER'S MANUAL FOR STRUCTURED LEARNING THERAPY; plus a set of Trainer Preparation Tapes,
0 08 021113 5.....$50.00

Awake on the job...

yet anxiety controlled

Troublesome drowsiness uncommon

Tranxene lets you manage anxiety in most patients without problem sedation. Any initial drowsiness is usually transient.

Calming without impairment

Patients not oversedated can function better on the job* or at home. By avoiding excessive sedation, Tranxene helps you calm patients without compromising their capacities.

Tranxene® CIV

(CLORAZEPATE DIPOTASSIUM) 4306CB

CAPSULES,
SINGLE DOSE TABLETS

Brief Summary

ACTIONS — Pharmacologically, clorazepate dipotassium has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine. (See CLINICAL PHARMACOLOGY section.)

INDICATIONS — TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS — TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS — TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS — In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS — The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION

For the symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose dail bedtime; the recommended initial dose is 15 mg. After the initial dose, response of the patient may require adjustment of subsequent dos Lower doses may be indicated in the elderly patient. Drowsiness may o at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single every 24 hours. This tablet is intended as an alternate dosage form fo convenience of patients stabilized on a dose of 7.5 mg. capsules three t a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be ministered as a single dose every 24 hours.

For the symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg. TRANXENE initially, follo by 30 to 60 mg. in divided doses; 2nd 24 hours, 45 to 90 mg. in div doses; 3rd 24 hours, 22.5 to 45 mg. in divided doses; 4th day, 15 to 30 in divided doses. Thereafter gradually reduce to 7.5 to 15 mg. daily, discontinue as soon as condition is stable. Maximum daily dose is 90 Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS — If TRANXENE is to be combined with other d acting on the central nervous system, careful consideration should be g to the pharmacology of the agents to be employed. Animal experience cates that TRANXENE prolongs the sleeping time after hexobarbital or ethyl alcohol, increases the inhibitory effects of chlorpromazine, but not exhibit monoamine oxidase inhibition. Clinical studies have show creased sedation with concurrent hypnotic medications. The actions o benzodiazepines may be potentiated by barbiturates, narco phenothiazines, monoamine oxidase inhibitors or other antidepressan

If TRANXENE is used to treat anxiety associated with somatic dis states, careful attention must be paid to possible drug interaction with comitant medication.

MANAGEMENT OF OVERDOSAGE — Overdosage is usually manifeste varying degrees of CNS depression ranging from slight sedation to com in the management of overdosage with any drug, it should be borne in that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatme overdosage should consist of the general measures employed in the agement of overdosage of any CNS depressant. Gastric evacuation eith the induction of emesis, lavage, or both, should be performed immedi General supportive care, including frequent monitoring of the vital and close observation of the patient, is indicated. Hypotension, th rarely reported, may occur with large overdoses. In such cases the u agents such as Levophed® (levarterenol) or Aramine® (metaraminol) s be considered.

While reports indicate that individuals have survived overdos TRANXENE (clorazepate dipotassium) as high as 450 to 675 mg., doses are not necessarily an accurate indication of the amount of dru sorbed since the time interval between ingestion and the institution of ment was not always known. Sedation in varying degrees was the common physiological manifestation of TRANXENE overdosage. Deep when it occurred was usually associated with the ingestion of other dr addition to TRANXENE.

CLINICAL PHARMACOLOGY — Studies in healthy men have shown TRANXENE has depressant effects on the central nervous sy Prolonged administration of single daily doses as high as 120 mg without toxic effects. Abrupt cessation of high doses was followed in patients by nervousness, insomnia, irritability, diarrhea, muscle ach memory impairment.

Absorption — Excretion:

After oral administration of TRANXENE, there is essentially no circu parent drug. Nordiazepam, its primary metabolite, quickly appears blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRAN about 80% was recovered in the urine and feces within 10 days. Exc was primarily in the urine with about 1% excreted per day on day 1

HOW SUPPLIED — TRANXENE (clorazepate dipotassium) is suppli capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 30 0074-3418-30), 100 (NDC 0074-3418-13) and 500 (NDC 0074-341 Also available in ABBO-PAC unit dose packages of 100 capsules 0074-3418-11).

15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) ar (NDC 0074-3419-53). Also available in ABBO-PAC unit dose packa 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage stren

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in of 30 (NDC 0074-2699-30) and 100 (NDC 0074-2699-13).

The Office of Continuing Medical Education
Albert Einstein College of Medicine

Announces Two Courses

Clinical Neurology For Psychiatrists:
Part 1 and Part 2

Under the Direction of

David M. Kaufman, M.D.

Department of Neurology
Montefiore Hospital and Medical Center

Part 1. Friday, Saturday, and Sunday; March 23, 24 and 25. This course, designed for psychiatrists preparing for the written part of the **American Board of Psychiatry and Neurology**, will consist of a series of lectures, videotaped demonstrations, and a practice written examination. **30 hours of Category 1 credit will be awarded.**

Part 2. Saturday and Sunday; October 6 and 7. the continuation, a course for candidates for the oral section of the Board, will review major neurological disorders by presenting audiovisual demonstrations and practice examinations. **20 hours of Category 1 credit will be awarded.**

FOR FURTHER INFORMATION CONTACT:

The West Virginia University School of Medicine

Announces its First Annual Behavorial Medicine Conference

"Communication and Compliance In a Hospital Setting"

To be held at the

LAKEVIEW COUNTRY CLUB
Morgantown, West Virginia
on
April 20 and 21, 1979

The Conference will be sponsored by: The Department of Medicine, The Department of Behavorial Medicine and Psychiatry, The Office of Continuing Education and The W.V.U. Foundation, Incorporated.

FACULTY WILL INCLUDE:

Eric Cassell, M.D.
Clinical Professor of Public Health — Cornell

James L. Strain, M.D.
Assoc. Clinical Professor — Albert Einstein

Wilford W. Spradlin, M.D.
Professor & Chairman — U.Va.

Patricia Porterfield, M.S.W.
Associate Professor — U.Va.

Ruth Purtilo, R.P.T., M.T.S.
Assistant Professor — U.Mass
(Lv. of absence)

Robert E. Pawlicki, Ph.D.
Assoc. Prof. — SUNY, Oswego

David J. Whithersty, M.D.
Assoc. Prof. & Assistant Chairman — WVU

Raymond Kidwell, M.D.
Resident — WVU

Shawn Chillag, M.D.
Assistant Professor — WVU

Richard Seime, Ph.D.
Associate Professor — WVU

Registration Fees: $60.00 — Physicians
30.00 — Non-M.D. Professionals

AMA Category 1 CME Credits: 9 AAFP Credits applied for.

Registration will be limited to 150. Contact:

NEW

An outstanding new volume from the publishers of AMA Drug Evaluations, 3rd Edition

SUICIDE: Theory and Clinical Aspects

Edited by Leon D. Hankoff, MD, State University of New York at Stony Brook School of Medicine and Bernice Einsidler, MS, New York Medical College

An enlightened view of attempted and successful suicide, with particular emphasis on prevention and treatment. This exceptional new volume explores the history of suicide as well as contemporary ethical, religious, and legal concerns, plus—

- **Biology of Suicide and the Suicidal Person**—Personality, motivation, behavior theory, life stress
- **Specific Risk Subgroups**—The aged, alcoholics, general hospital patients, physicians, and others
- **Management and Prevention**—By medical practitioners, religious advisors, and suicide prevention agencies

New! **400 pages, illustrated** **$32.50**

Available directly from the publisher on 15-day approval, or from your local bookseller.
Order toll-free — 800/225-5020. In Massachusetts, call collect, 617/486-8971.

This is probably your first look at

Actual case photographs by Theodore Spagna.

Photographs of a normal subject experiencing a night of sleep.

ght of sleep

The photographs above reflect 15-minute intervals in a night of sleep at home. This "sleep portrait" is extraordinary because time-lapse photography, available since the 1880's, has never before been used to objectify human sleep. This innovative technique is less expensive than sleep laboratory evaluation, and paves the way for future field research. In the home, the intervalometer-controlled camera captures many naturalistic features of sleep behavior available only to direct observation; the rich behavioral data it records serve to complement those of the sleep laboratory, and may prove to have important significance in sleep research. This is a first step toward an ethology of sleep; it represents the joint efforts of Allan Hobson, M.D., and Theodore Spagna, photographer, sleep researchers at Harvard University.*

*Hobson A, Spagna T: Time-lapse photography and the ethology of sleep. *Sleep Res* 5:210, 1976.

Please see following page for a summary of product information.

ROCHE

Take a closer look at...

DURATION OF SLEEP LONGER: 7 TO 8 HOURS, ON AVERAGE

...as proved by nightlong electrophysiologic evidence of increased total sleep time in insomniac subjects in eight sleep laboratory studies.[1]

ASLEEP FASTER: ON AVERAGE, WITHIN 17 MINUTES

...as proved in the same eight studies.[1] Of the hypnotics studied, only Dalmane (flurazepam HCl) improved all three parameters: sleep induction, number of nighttime awakenings and total sleep time.

LONGER EFFICACY: 28 CONSECUTIVE NIGHTS

...of relief from chronic insomnia, as proved in one study using an original 47-night protocol[2] and confirm in another.[3] (Prolonged adm istration, though seldom necessary, should be moni-tored by periodic blood cou and liver and kidney functio tests.)

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).
Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit initial dosage to 15 mg to preclude oversedation, dizziness and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until respons is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

MORE OBJECTIVE DOCUMENTATION THAN ANY OTHER AVAILABLE HYPNOTIC

proved more effective than oral hydrate,[4,5] glutemide,[4,5] pentobarbital[2] d secobarbital[5,6] — over 14 hts of administration in the ep laboratory.

AWAKENINGS SHORTER AND LESS FREQUENT

...after sleep onset, without repeating dosage during the night.[1] The usual adult dosage is 30 mg *h.s.*, 15 mg may suffice in some patients.

NO DOSAGE INCREASE FROM NIGHT TO NIGHT

...for continued effectiveness in chronic insomnia.[2,3] Sleep induction and maintenance are provided by one *h.s.* dosage for 28 nights if necessary. Generally well tolerated, Dalmane (flurazepam HCl) seldom causes morning "hang-over."

EFFECTIVENESS OBJECTIVELY PROVED IN ELDERLY INSOMNIACS

...at 15 mg: this dosage (recommended to *initiate* therapy in the elderly or debilitated to help preclude oversedation, dizziness or ataxia) provided elderly insomniacs with 83 additional minutes of sleep, on average, in the sleep laboratory.[7]

Helps weather
the manic storm

maintenance therapy with Eskalith® 300 mg capsules

brand of

lithium carbonate

In manic-depressive patients with a history of mania, 'Eskalith'

prevents or diminishes the intensity of future episodes

can increase the intervals between episodes

helps patients function within normal limits

efore prescribing, see complete prescribing information in SK&F terature or PDR. The following is a brief summary.

WARNING
Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

ndications: Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent pisodes in manic-depressive patients with a history of mania.

Warnings: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, odium depletion, or to patients receiving diuretics.

ithium therapy has been reported in some cases to be associated with orphologic changes in the kidneys.

aution patient and family to watch for diarrhea, vomiting, tremor, mild axia, drowsiness, or muscular weakness as signs of lithium toxicity, nd to discontinue therapy and contact a physician should they occur. atients receiving combined therapy with lithium and an antipsychotic ould be monitored closely for early evidence of neurologic toxicity nd treatment discontinued promptly if such signs appear. Caution atients about activities requiring alertness (e.g., operating vehicles or achinery).

thium should not be used in pregnancy, especially during the first mester, unless potential benefits outweigh possible hazards.

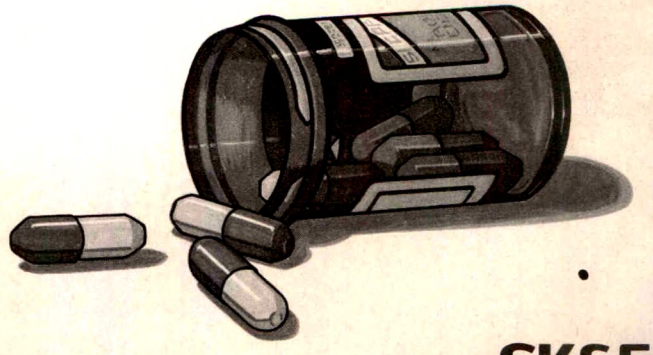
ot recommended for children under 12.

recautions: Lithium tolerance is greater during the acute manic phase nd decreases when manic symptoms subside.

thium therapy may lead to sodium depletion. Normal diet (including lt) and adequate fluid intake (2500-3000 ml.) must be maintained, at ast during initial stabilization period. Protracted sweating or diarrhea n decrease tolerance; in such cases, administer supplemental fluid d salt.

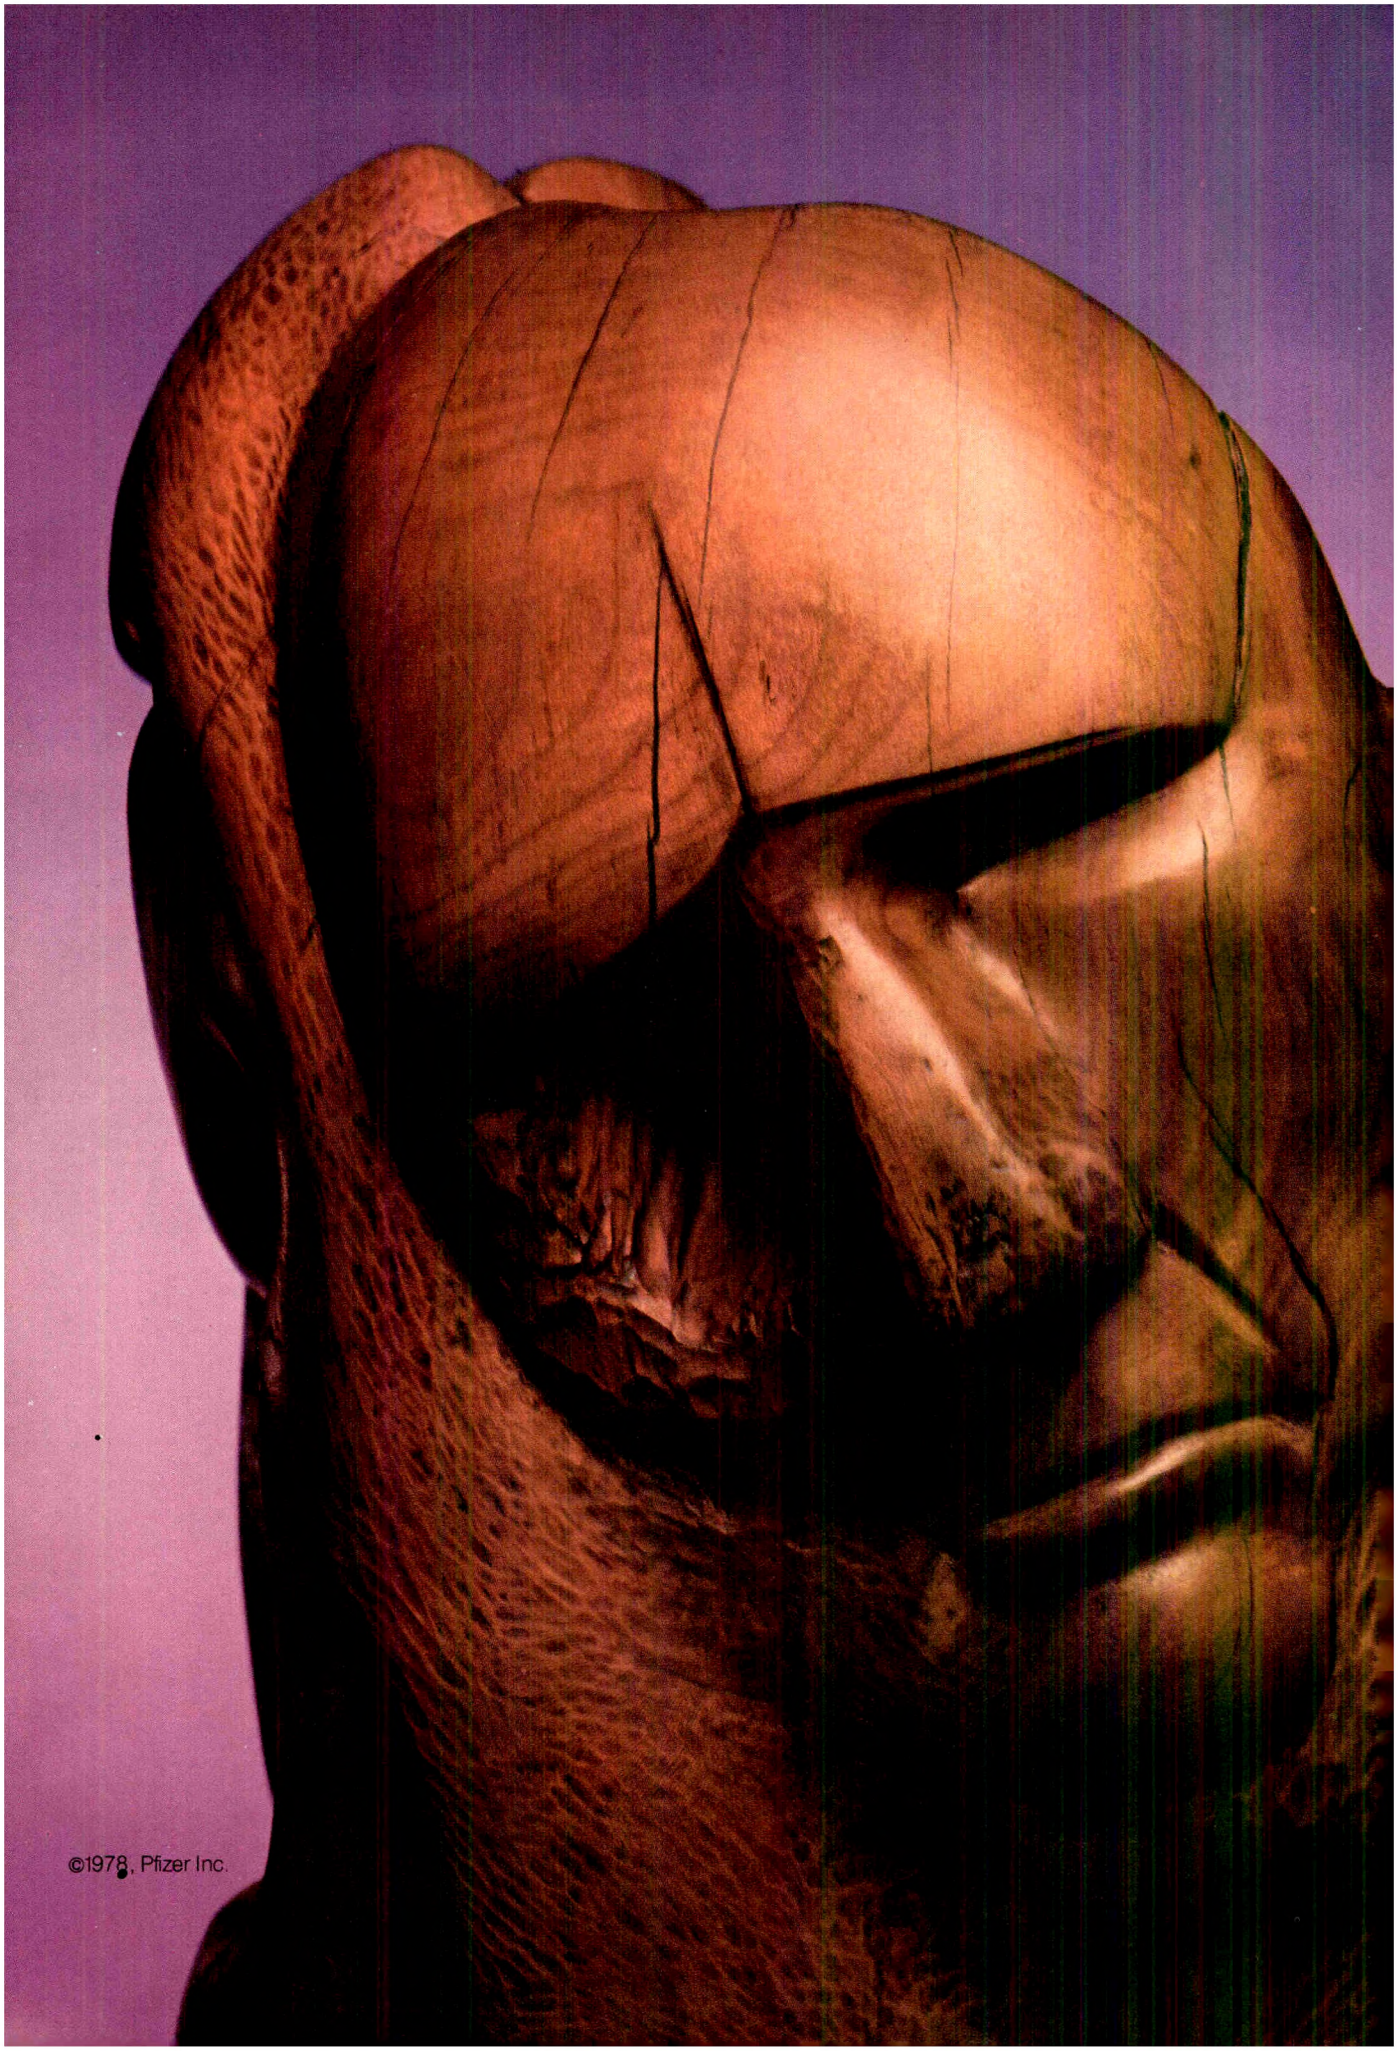
veating, diarrhea, and concomitant infection with elevated temperares may require temporary reduction or cessation of dosage.

dverse Reactions: Mild to moderate toxic reactions may occur at rum lithium levels from 1.5 to 2.5 mEq./l., and moderate to severe actions at levels from 2.0 to 2.5 mEq./l. Fine hand tremor, polyuria, d mild thirst may occur during initial therapy and persist. Transient d mild nausea and general discomfort also appear during initial erapy. These effects usually subside with continued treatment or mporary reduction or cessation of dosage. If persistent, discontinue sage.

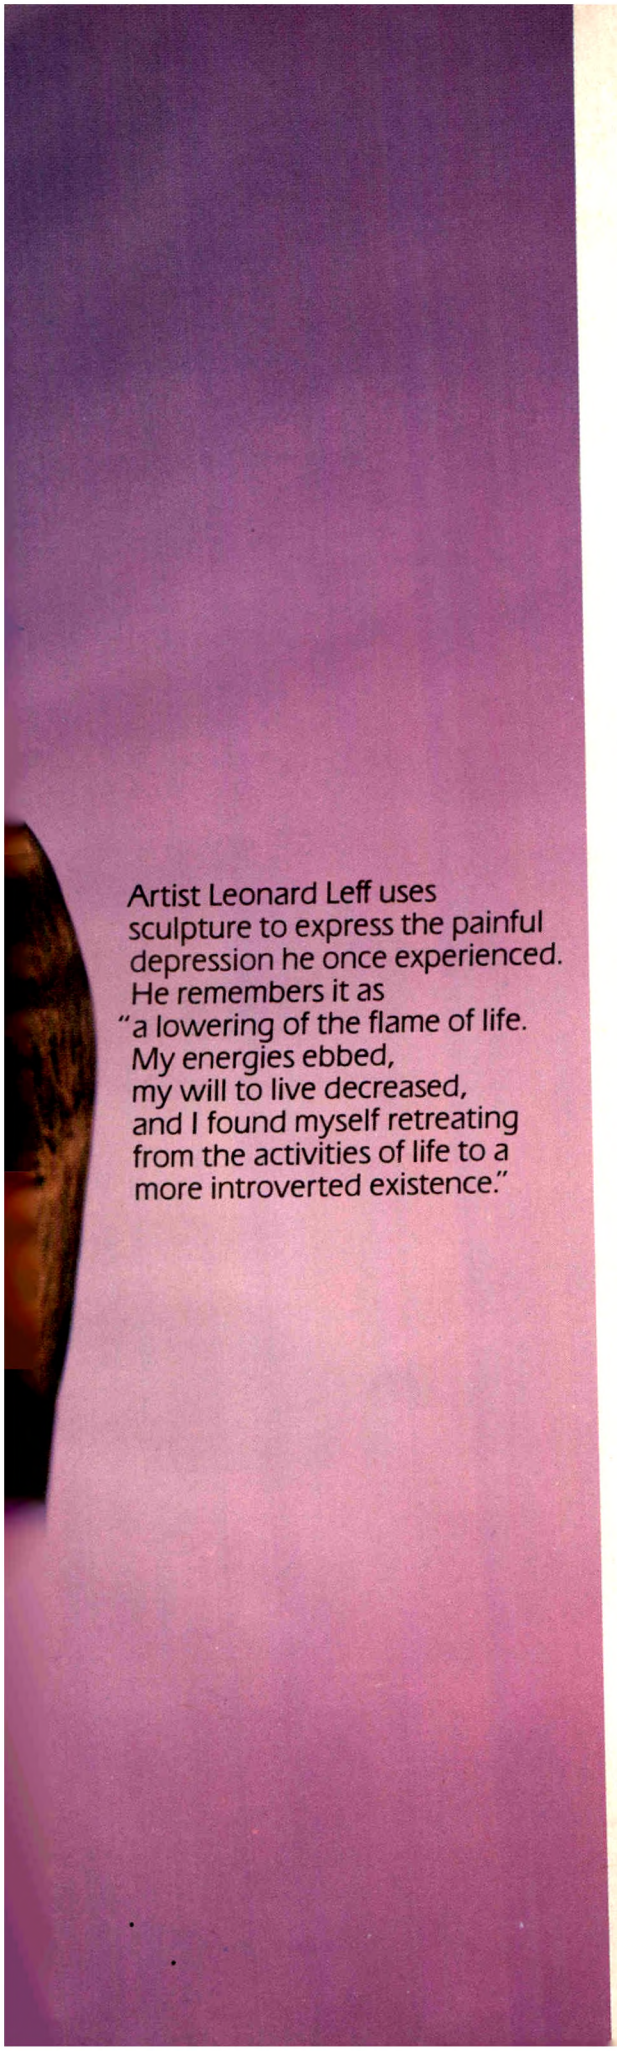


arrhea, vomiting, drowsiness, muscular weakness, and lack of coordition may be early signs of toxicity and may occur at levels below) mEq./l. At higher levels, ataxia, giddiness, tinnitus, blurred vision, d a large output of dilute urine may be seen. Serum levels above) mEq./l. may produce a complex clinical picture, involving multiple gans and systems. Serum levels should not exceed 2.0 mEq./l. during ute phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range: **Neuromuscular**—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflex; **Central Nervous System**—blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma; **Cardiovascular**—cardiac arrhythmia, hypotension, peripheral circulatory collapse; **Gastrointestinal**—anorexia, nausea, vomiting, diarrhea; **Genitourinary**—albuminuria, oliguria, polyuria, glycosuria; **Dermatologic**—drying and thinning of hair, alopecia, anesthesia of skin, chronic folliculitis, exacerbation of psoriasis, xerosis cutis; **Autonomic**—blurred vision, dry mouth; **Thyroid Abnormalities**—euthyroid goiter and/or hypothyroidism (including myxedema) with lower T_3 and T_4. I^{131} uptake may be elevated; **EEG Changes**—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; **EKG Changes**—reversible flattening, isoelectricity or inversion of T-waves; **Miscellaneous**—fatigue, lethargy, transient scotomata, dehydration, weight loss, tendency to sleep.



Reactions unrelated to dosage include: transient EEG and EKG changes, leukocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, thirst or polyuria, sometimes resembling diabetes insipidus, and metallic taste. A single case of a syndrome resembling Raynaud's has been reported.



How Supplied: 300 mg. capsules in bottles of 100.

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

CONVENIENT ONCE-A-DAY *h.s.* DOSAG

which may improve patient compliance. The to daily dosage, up to 150 mg per day, may be giv on a once-a-day schedule without loss of effec- tiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per da

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accom panies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does n generally affect the antihypertensive activity of guanethidine and related compounds. Tachy- cardia and hypotension have been reported occasionally. Drowsiness is the most commonly served side effect. Dry mouth, blurred vision, con pation and urinary retention have been reporte

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate sev starting daily dose of 75 mg is recommended. Dosage may subsequently be increa decreased at appropriate intervals and according to individual response. The usual o dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual incr 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exce dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying o disease, lower doses may suffice. Some of these patients have been controlled on doses as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once dosage schedule. If the once-a-day schedule is employed the maximum recommended 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intend maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmia tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggre supportive therapy. If the patient is conscious, gastric lavage, with appropriate precauti prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly abs The use of activated charcoal has been recommended, as has been continuous gastric l with saline for 24 hours or more. An adequate airway should be established in comatose pa and assisted ventilation used if necessary. EKG monitoring may be required for several since relapse after apparent recovery has been reported. Arrhythmias should be treated wi appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow venous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigm rapidly metabolized, the dosage should be repeated as required. Convulsions may respo standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory de sion. Dialysis and forced diuresis generally are not of value in the management of overdo due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 7 and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 m 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 15 doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calib at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 1 doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, pru pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a numb carbonated beverages. For those patients requiring antidepressant therapy who ar methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be m together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not grape juice. Preparation and storage of bulk dilutions is not recommended.

More detailed professional information available on request.

Pfizer **LABORATORIES DIVISION**
PFIZER INC.

a consideration beyond efficacy alone...

Infrequent akathisia and other disabling extrapyramidal effects...

The rapidly rising readmission rate among discharged psychotic patients is mainly due to noncompliance with antipsychotic drug therapy. And this, in turn, may be largely attributed to disabling extrapyramidal side effects, notably akathisia.[1]

Although extrapyramidal effects are characteristic of antipsychotic agents in general, with Mellaril (thioridazine) such effects are infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided. Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

Extrapyramidal Effects of Selected Antipsychotic Agents*[2]

DRUG	EXTRAPYRAMIDAL EFFECTS
Chlorpromazine	Moderate
Perphenazine	High
Prochlorperazine	High
Fluphenazine	High
Acetophenazine	Moderate
Trifluoperazine	High
Chlorprothixene	Moderate
Thiothixene	Moderate
Haloperidol	High
MELLARIL® (thioridazine)	Low

*Based on antipsychotic dosage ranges

Mellaril® (thioridazine)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

MELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml: thioridazine base equivalent to 100 mg thioridazine HCl, USP

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

THE AMERICAN JOURNAL OF PSYCHIATRY

Overview: Efficacy and Safety of the Rapid Neuroleptization Method with Injectable Haloperidol

BY PATRICK T. DONLON, M.D., JOHN HOPKIN, M.D., AND JOE P. TUPIN, M.D.

The authors review the literature on the rapid neuroleptization (titration) method with I.M. haloperidol. Most of the approximately 650 predominantly schizophrenic and manic patients represented in the studies calmed down rapidly on medication, and some demonstrated an early reduction in core psychotic symptoms. The initial doses varied widely, ranging from 1 to 30 mg, with a maximum total daily dosage of 100 mg. The medication seemed to have been well tolerated in all cases, with no reported major complications. The authors conclude that the method shows definite merit with agitated and belligerent patients. However, they make a number of specific recommendations for further research to clearly establish the effectiveness and safety of this method of neuroleptic administration.

THE RAPID NEUROLEPTIZATION (titration) technique is a method of administering repeat doses of neuroleptic medication under close clinical supervision that provides rapid control of acute functional psychotic symptoms in most patients. The technique is an important landmark because agitated and belligerent patients are often seen clinically. Rapid symptom control not only relieves distressing symptoms but also greatly reduces the risk of injury to self and others.

The advocates of the technique recommend administering I.M. medication every 30–60 minutes until symptoms are controlled (1, 2). Parenteral medication is preferred over oral medication because the former works faster and the more potent neuroleptics are preferred over chlorpromazine because of their greater cardiovascular safety, reduced sedation, and absence of pain at the injection site. Although many potent agents have been used, haloperidol has been the most extensively evaluated and reported. Clinically, 1–4 injections of 2.5–10.0 mg each are normally required to produce rapid control. The patient is then switched to oral medication.

In this paper we will review the published reports on injectable haloperidol in acute psychotic states and critically evaluate the clinical findings of the rapid neuroleptization technique. More specifically, we will focus on both medical and nonmedical factors that must be carefully evaluated before unequivocally establishing the effectiveness of the rapid titration method in the treatment of schizophrenia.

LITERATURE REVIEW

Open Studies

Danik and Goverdham (3) reported the successful use of parenteral haloperidol administered in 10-mg doses to initiate treatment of psychotic patients. They had a favorable experience treating acute manic and schizophrenic patients with both intravenous and intramuscular haloperidol in total daily dosages up to 25 mg. Nearly all of their patients showed symptom remission within 24 hours. Medication was well tolerated, and adverse effects were predominantly extrapyramidal symptoms.

Oldham and Bott (4) administered I.M. haloperidol to 124 patients, using initial doses of 10–30 mg to control excitement. With total daily doses of 20–40 mg, 73% of Oldham and Bott's patients (91 of 124) were stabilized, usually within 72 hours. Of the remainder, 27 patients (22%) were partly controlled and only 6 (5%) did not respond at all. The patients whose symp-

toms were controlled by parenteral haloperidol were then given oral haloperidol and orphenadrine hydrochloride in diminishing doses to maintenance levels. The treatment regimen had to be discontinued and replaced by another in only 6 of the 124 patients. Four of these 6 had not responded; 1 had severe dystonia, and 1 had transient hypotension (90/60 mm/Hg). Oldham and Bott recommended using haloperidol in doses of 20–30 mg initially to control psychotic excitement because its margin of safety permitted use in all but the frailest patients.

Feldman and associates (5) administered 5 mg of I.M. haloperidol 3 times daily, generally for a maximum of 3 days, to 25 inpatients suffering from acute psychotic episodes or exacerbations. Clinical evaluation after 3 days of treatment showed a significant improvement in the areas of affect, social behavior, motor behavior, perception, ideation, and sensorium. The main side effects were extrapyramidal symptoms, but these were easily controlled.

Sangiovanni and associates (6) administered I.M. injections of haloperidol (10–30 mg) 1–3 times daily as part of the initial treatment of 40 acutely disturbed psychotic inpatients. A maximum of 60 mg was administered daily to each patient. A wide range of therapeutic doses titrated to response in individual patients resulted in marked or moderate control of symptoms in 36 of the 40 patients (90%) in 72 hours. Fourteen patients (35%) were controlled by parenteral haloperidol in doses totaling less than 30 mg; 14 patients (35%) were controlled by 30–60 mg; and 8 patients (20%) required more than 60 mg. Four patients (10%) responded only minimally and required other treatment.

The adverse reactions of the patients in this study were unexceptional. Lethargy lasting several hours was noted in approximately a third of the patients on the first day of treatment. At low doses (less than 20 mg), parkinsonism developed in 6 patients and coarse tremor of the hand developed in 5 others. Dystonic reactions in 4 other patients were rapidly relieved by treatment with antiparkinsonian agents.

Carter (7) retrospectively tabulated and analyzed the outcome of 48 acutely disturbed psychotic patients receiving parenteral haloperidol. Except for a massively obese, excited, manic man who received an initial dose of 20 mg, all of these patients received 5–10 mg at 30–60-minute intervals. Thirty-six of the 48 patients received a total of 40 mg or less of parenteral haloperidol over 24 hours. The remaining 12 patients received a total of 45–100 mg I.M. over 24 hours.

The therapeutic response was determined by comparing the severity of psychomotor agitation, hostility and belligerence, auditory hallucinations, and flight of ideas at pretreatment and posttreatment. Within 2 hours of treatment initiation all ratings were significantly reduced. Only 18 patients had residual symptoms at 4 hours, and only 4 of the 48 patients (8%) responded minimally or not at all to the treatment. Extrapyramidal symptoms, predominantly dystonia or cogwheel rigidity, occurred in 14 subjects at total doses between 5 and 30 mg. Transient hypotension occurred in 3 cases. Sedation was not characteristic, but 16 subjects slept following symptom relief.

Firling (8) administered parenteral haloperidol to 169 chronic psychotic patients who were experiencing symptom exacerbation, usually associated with the discontinuation of neuroleptic medication. All were acutely disturbed and often belligerent. These patients, 124 men and 45 women, were diagnosed as follows: 130 had schizophrenia, 20 had manic-depressive psychosis, 10 had drug-abuse-induced psychosis, and 9 had other diagnoses. One hundred twenty-five of the subjects required a single 10-mg injection, and 23 required a single 5-mg injection. The remaining 21 patients required 2–4 injections of 10 mg of haloperidol given at 30-minute intervals.

The outcome was determined by a retrospective review of case records. Within 20 minutes after the first injection, psychomotor agitation was significantly reduced in 157 patients and hostility and belligerence were reduced in 136 patients. The related signs and symptoms of psychosis were also reduced.

The medication was tolerated in all cases without undue sedation or hypotensive reactions. Sixteen subjects developed extrapyramidal symptoms (12 with dystonia) that remitted either spontaneously or after administration of 2 mg of contra-active trihexyphenidyl orally.

In a study of injectable haloperidol that is being prepared by Hopkin, Donlon, and Schaffer, 2.5–10 mg of I.M. haloperidol was administered every 30 minutes as needed over a 6-hour evaluative period with 25 newly admitted, hospitalized, acute schizophrenic patients. The sample consisted of 8 women and 17 men with a mean age of 26 and a mean dosage of 23 mg.

Most of the patients responded rapidly to treatment. The patients demonstrated the following improvement at the 6-hour clinical global improvement rating: marked, 6; moderate, 11; slight, 5; and no change, 3. For the group as a whole, significant reduction occurred in excitement and belligerence as well as in core pathological signs and symptoms (thought disorganization, delusions, hallucinations, and suspiciousness). One patient developed dystonia, 1 patient developed mild transient and asymptomatic hypotension, and 5 patients experienced sedation. The cardiovascular safety of the technique was further documented by monitoring vital signs every 30 minutes on all subjects and obtaining Holter monitors on 6 subjects. No significant changes were identified.

Double-Blind Studies

Man and Chen (9) administered I.M. injections of 5 mg of haloperidol to 15 acutely disturbed psychotic adults and 50 mg of chlorpromazine to 15 others. Up to 7 injections were administered at 20-minute intervals until the patients were no longer assaultive or manic or until it was evident that further injections would be of no therapeutic benefit. Two or 3 injections were re-

quired in most of the cases (N=16). The results were evaluated by the Rating Scale for Target Symptoms (mania, agitation, hostility) (9) and the Brief Psychiatric Rating Scale (BPRS). In patients treated with haloperidol, the values for the severity of target symptoms were reduced by approximately half in an average of 2 hours. The total BPRS mean score was reduced by 45% from a pretreatment mean value of 56 to an adjusted final mean of 31. The results with chlorpromazine were similar, although an average of 2½ hours was required for equivalent reductions.

Two patients treated with chlorpromazine were removed from the study after severe hypotensive reactions. One of these reactions occurred after 1 injection of 50 mg of chlorpromazine. The other occurred after 2 injections of 50 mg. In both cases, blood pressure was not obtainable and was restored only after intensive emergency measures. In another patient who received chlorpromazine, the development of status epilepticus necessitated treatment with anticonvulsants. There were no adverse reactions among the patients given haloperidol.

Follow-up evaluation on day 3 showed that patients whose symptoms were controlled continued to improve after switchover to oral medication. These patients were transferred to a day hospital or discharged to an outpatient clinic for maintenance therapy. Man and Chen concluded that haloperidol was the safer agent for injection every 30 minutes and preferable to chlorpromazine for the treatment of acutely disturbed psychotic patients.

Reschke (10) compared parenteral haloperidol (1, 2 or 5 mg) with chlorpromazine (25 mg) and with a placebo control in the management of disruptive behavior in adults with acute schizophrenia. A total of 50 patients were treated in five groups of 8–11 patients each. The drugs and placebo were administered I.M. every 30 minutes until agitation, excitement, and assaultiveness were controlled or until a maximum of 4 injections were given. An analysis of global evaluations and BPRS scores indicated that control was significantly ($p<.05$) greater in patients who received haloperidol in doses of 2 or 5 mg than in those who received doses of 1 mg of haloperidol, 25 mg of chlorpromazine, or placebo. The largest reduction in BPRS signs and symptoms occurred in the 10 patients who received 5 mg of haloperidol every 30 minutes; an average of 2.8 injections of this dose reduced pretreatment BPRS values by 42%.

The side effects of the drugs were minimal in this study. Systolic blood pressure was reduced transiently from normal to less than 100 mm/Hg in 2 patients, 1 of whom received a total of 10 mg of haloperidol and the other a total of 50 mg of chlorpromazine. Drowsiness was evident in 13 of the 29 patients who received haloperidol (45%), but only 1 fell asleep during the 2-hour test period. However, 6 of the 10 patients who received chlorpromazine and none of the 11 who received placebo fell asleep. Reschke concluded that 2 or 5 mg of I.M. haloperidol was superior to the other regimens tested in the control of disruptive behavior in acute schizophrenic patients.

Anderson and associates (11) treated 14 acutely psychotic patients with 10 mg of I.M. haloperidol every 30 minutes and another 10 patients with 5 mg of haloperidol every 60 minutes. Both regimens rapidly controlled disruptive behavior within 3 hours after the first injection (7 of the 14 patients receiving 10-mg doses and 4 of the 10 receiving 5-mg doses). Another 5 patients improved markedly within 72 hours. Of the remaining 8 patients, 5 were dropped from the study and 3 others improved after more than 72 hours. In addition to calming the patients, haloperidol significantly reduced the severity of the signs of psychosis, specifically hallucinations, unusual thought content, suspiciousness, conceptual disorganization, and grandiosity. In both test groups, mean scores on the BPRS were reduced from pretreatment values of 57–66 to less than 30. In this study marked remission was not evident at total doses under 15 mg, and additional improvement was not evident in patients who received total doses higher than 45 mg.

The side effects of haloperidol were mild and occurred equally in patients in either regimen; none was unusual or required discontinuation of the regimen. Extrapyramidal signs in 8 patients were controlled with 2 mg of I.M. benztropine mesylate followed by oral medication if necessary. Eight patients were drowsy but in no case sedated to the point that they could not be interviewed.

The study demonstrated the feasibility of bringing about remission in patients with acute psychosis within a few hours and also the need for flexible dosage: some moderately disturbed patients required high doses for relief of symptoms and many severely disturbed patients did not. This has been Anderson and Keuhnle's clinical experience and the basis of their recommendation (12) to use 5–10 mg of parenteral haloperidol every 30 to 60 minutes for the rapid control of sudden onset psychosis.

Gerstenzang and Krulisky (13) compared parenteral haloperidol and chlorpromazine in 58 patients brought to an emergency room for disruptive behavior. The symptom pictures of these patients ranged from marked agitated behavior to marked negativism and withdrawal. Approximately half of the patients were given a provisional diagnosis of schizophrenia. The subjects were evaluated 30 to 60 minutes after a single injection of 5 mg of haloperidol or 50 mg of chlorpromazine.

Half of the 30 patients receiving haloperidol became calm, cooperative, and alert, and another 8 of these patients improved. In contrast, only 3 of the 28 chlorpromazine patients were controlled successfully, and 11 were partly controlled. Covariant analysis of BPRS scores significantly favored haloperidol for conceptual disorganization, tension, hostility, uncooperativeness, and excitement. None of the statistical comparisons favored chlorpromazine. No adverse reactions, including hypotension and extrapyramidal symptoms,

occurred during the brief evaluation period.

Levenson and associates (14) administered single daily doses of parenteral fluphenazine HCl, thiothixene, or haloperidol to newly hospitalized acute schizophrenic patients to compare efficacy and speed of recovery. The doses were predetermined and equipotent and were given I.M. each day at 9:00 a.m. Initial doses were 2.5 mg for fluphenazine HCl and haloperidol and 5 mg for thiothixene. By day 4 the doses were gradually elevated and fixed at 7.5 mg and 15 mg, respectively. The study period lasted 21 days, but patients who responded optimally were terminated early.

Seventeen patients started the investigation, but 5 received administrative discharge before symptom remission and were not in the data analysis. With this small sample size no significant differences were found using the Kruskal-Wallis test, although a definite trend favored haloperidol for speed of recovery. The overall rate of remission for all groups combined was 83%. Side effects were similar for all three groups and were limited to extrapyramidal symptoms.

Paprock and Versiani (15) compared parenteral loxapine with haloperidol in 35 acutely and severely ill newly hospitalized schizophrenic patients. Seventeen patients were treated for 4 days with loxapine in a mean daily dosage of 115.4 mg (range, 87.5–125 mg), and 18 patients were treated with haloperidol in a mean daily dosage of 11.5 mg (range, 8.8–12.5 mg). Progress was monitored using daily BPRS, NOSIE, and clinical global impression rating scales. Laboratory determinations included complete blood count, urine analysis, and chemistries. Vital signs were monitored, and adverse effects were assessed and recorded.

A few significant differences were found using analysis of covariance. Loxapine demonstrated some superiority in the reduction of agitated/excited and aggressive behaviors. According to global assessment 10 of the 17 loxapine patients and 15 of the 18 haloperidol patients improved. Adverse effects were similar for both groups and were predominantly extrapyramidal symptoms and drowsiness.

The 25 patients who responded favorably were switched to oral medication for a 4-week assessment period; the same rating scales were used. The switchover was made on an equal mg-for-mg basis. After 3 days, dosage was left open and dependent on clinical response up to maximum daily dosages of 150 mg of loxapine and 15 mg of haloperidol. Improvement was considerable and comparable for the two groups given oral medication.

Stotsky (16) treated 30 acutely psychotic, agitated outpatients with either I.M. haloperidol or I.M. thiothixene. Patients received 4 mg or 8 mg of thiothixene or haloperidol every hour as needed during a 4-hour treatment program. An additional 2-hour period was allowed for further observation and ratings for a total 6-hour evaluative period.

The total mean dosage for the 15 haloperidol patients was 15 mg (range, 8–32 mg); for the 15 thiothixene patients it was 10.1 mg (range, 4–16). All 30 patients achieved rapid tranquilization and significant improvement on the total BPRS score, the 4 BPRS factors, and the 17 symptoms of the Psychiatric Target Symptom Profile (16). Side effects were few and similar for both groups, the most frequent being drowsiness. Analysis of covariance demonstrated no significant differences between the two groups for efficacy or time required to control symptoms.

DISCUSSION

Striking in this review is the consistency of the reports of favorable and rapid therapeutic outcome for parenteral haloperidol in reducing acute excitement and agitation in psychotic patients. Some authors also reported a reduction in the core symptoms of schizophrenia and mania. Although most of the patients were schizophrenic, the method appears effective for other acute psychotic states as well. Relative safety was reported in all subjects; the most common adverse effects were extrapyramidal symptoms, sedation, and transient hypotension. No major treatment complications were reported for the approximately 650 subjects taking haloperidol who were receiving initial doses in the range of 1–30 mg I.M. and total daily dosages up to 100 mg I.M.

However, many methodological shortcomings in these studies make the data difficult to discuss. Most of the study periods lasted hours or a few days, making it difficult to precisely establish outcome and safety. Of note also, some of the studies lacked a placebo control to monitor nonmedical effects and spontaneous recoveries. The double-blind comparison studies should have allowed for differences in potency before claiming that haloperidol is efficaciously superior.

In spite of these shortcomings, the following guidelines may be summarized from the review:

1. Acute psychotic states may be associated with agitated and belligerent behavior that requires immediate medical attention to reduce the risk of injury to self or others and to provide greater comfort.

2. Injectable haloperidol is effective in rapidly controlling the signs and symptoms of acute psychotic excitement. Other neuroleptics when controlled for potency are probably equally effective.

3. Medication dosages must be highly individualized because dosage requirements cannot be predetermined by body weight, past requirements for neuroleptic dosage, presence and severity of particular target symptoms, or degree of psychotic impairment.

4. Individual doses normally range from 2.5–10.0 mg I.M., and patients typically require 1–4 injections given at 30–60-minute intervals.

5. The response to medication normally can be observed within minutes, minimizing the possibility of overdosing or cumulative medical effects.

6. In some schizophrenic and manic patients the reduction of excitement may also be associated with a

reduction in core psychotic symptoms (e.g., cognitive disorganization, hallucinations, and delusions).

7. The method is relatively safe, and the most common adverse effects are extrapyramidal symptoms, sedation, and hypotension.

8. Oral neuroleptics when indicated may be substituted following response to parenteral medication.

Ayd (2) has outlined guidelines for rapid I.M. neuroleptization (2). He stressed the importance of gathering historical data, evaluating general health, and establishing a preliminary diagnosis before initiating treatment. He further reported that I.V. neuroleptic therapy is preferable over I.M. in some patients. Our experience has been exclusively with I.M. neuroleptic therapy, so we cannot recommend I.V. therapy until its safety is further documented. In psychotic subjects who are toxic from psychedelic drugs or organic conditions with or without delirium, we have found that neuroleptics may potentiate the psychosis or mask developing medically important signs or symptoms. Thus the method should be reserved for physically healthy, excited schizophrenic or affectively disordered patients who require immediate symptom relief. Further, the least amount of medication should be given that will provide such relief.

Dosages and dosage schedules varied widely in the studies reviewed. The patient groups treated seemed to have been similar. Thus, the dosages administered might have reflected a bias toward a particular treatment regime among investigators rather than individual dosage requirements. That the outcomes were similar in all of these studies suggests that the medication is well tolerated in a wide range of dosages and without behavioral toxicity in higher dosages. The fact that most patients responded to the more conservative treatment suggests that the more aggressive use of medication should be withheld and used only as a backup treatment.

SUGGESTIONS FOR FURTHER RESEARCH

Further research is needed to answer the question of which patients are most likely to benefit from rapid I.M. neuroleptization with haloperidol. Most of the subjects selected for the studies reviewed were excited psychotic patients. The typical clinical response was a calming effect; some subjects demonstrated a reduction in core psychotic symptoms. It remains unclear whether the chronic schizophrenic patient and the acutely schizophrenic subject without dysphoric affect would benefit similarly. Furthermore, in patients who respond, do I.M. preparations act faster than oral neuroleptics in reducing core psychotic symptoms? Is the initial treatment response attributed to I.M. medication sustained after switching to oral neuroleptics? If so, are particular subgroups of patients involved? These questions may be more fully answered in well-controlled double-blind oral versus parenteral investigation that lasts for several weeks and that uses a heterogeneous clinical population of schizophrenic patients.

Another question requiring further research is, why is the I.M. rapid neuroleptization method effective? It has long been recognized that neuroleptics are effective in controlling psychotic states. However, some of the authors of the studies reviewed here strongly suggested that I.M. medication is more effective than oral preparations with acute patients. Are we dealing simply with patient selection factors? For example, it is well known that acute schizophrenic patients with dysphoric affect have a more favorable prognosis when given neuroleptics than more insidiously decompensated patients with a limited show of emotion. Certainly, the samples of patients in these studies consisted almost exclusively of those who were most likely to respond favorably to neuroleptics.

What about the effect of hospital and other emergency room influences (e.g., being removed from possible stress and placed in a protective environment) on the patient's overall response? Reschke's study (10), the only one that used a placebo control, demonstrated that an adequate dosage of a neuroleptic is significantly superior to a placebo injection, indicating that nonmedical influences are minor. Anderson and associates (11) also concluded that nonmedical influences are of minor importance. However, further studies like Reschke's, which compared an I.M. placebo versus an I.M. neuroleptic, are needed.

A third question for future research is, if the I.M. method is superior, why? Assuming that the pharmacological properties of parenteral and oral preparations of an agent are identical, then either the increased bioavailability or the rapid saturation of tissue at the site of action in the brain must account for the superiority of the I.M. method. Both would seem to favor I.M. preparation because I.M. absorption is faster and bioavailability is increased two- to threefold by eliminating the initial passage through the gut and liver and avoiding early metabolic breakdown. Thus, the excited patient who receives 15 mg of I.M. haloperidol over a 2-hour period may be receiving the equivalent of 40–50 mg orally. In fact, according to a personal communication from McNeil Laboratories in May 1976, if a 1-mg dose of haloperidol is administered orally and another parenterally, the patient's serum level in the first 20–30 minutes will favor the parenteral drug 10 to 1. After 24 hours these levels plateau to a 2 to 1 parenteral advantage. Thus, the early availability of higher amounts of the drug at the receptor sites provides for the rapid clinical response.

It remains unclear whether the dysphoric acute schizophrenic patient would respond equally to a comparably large dosage of oral medication. We hypothesized that this was precisely the case when we reported that treatment response could be accelerated by rapidly increasing the oral dosage of neuroleptic with acute schizophrenic patients (17). However, our preliminary research did not support this hypothesis (18). It is still of clinical interest to know if a particular

serum level is necessary for clinical response and if this response can be more readily obtained via oral or parenteral preparations. Although serum levels were not obtained in the studies reviewed, one can certainly conclude that dosage requirements vary widely among patients. Also, prescribing habits varied so widely in these studies that it is difficult to comment on dose-response relationships. Most patients seemed to demonstrate clinical response, and this often occurred only after repeat injections. However, some subjects were treatment failures in spite of large dosages. Thus, total dosage for optimal response varied widely and must be highly individualized. As Carter emphasized (7), high dosages should be administered only if there is a clear indication that they will be of therapeutic value.

Finally, haloperidol has long been recognized as a neuroleptic that rapidly controls excitement. Perhaps this effect is greater than that of other neuroleptics when controlled for potency. Clinically this is often assumed, i.e., haloperidol is often considered the agent of choice for acute mania. However, in the comparisons cited above with I.M. loxapine (15), fluphenazine (14), and thiothixene (14, 16), outcome was similar, and in the comparison studies with chlorpromazine outcomes may have been similar for efficacy if dosages had been better controlled for potency (9, 10, 13).

The problem with switchover to oral agents is another subject requiring further research. According to our clinical experience switchover to oral agents may be problematic. However, this topic received little attention in the studies reviewed. Ayd (2) recommended doubling the total I.M. dose required in the first 24 hours to achieve symptomatic control. Mason and Granacher (1) recommended increasing the oral dosage up to half that required for I.M. control. These guidelines are helpful, but they should be considered rough approximations. Clinically, if one follows these guidelines some patients will become overmedicated and others will show signs of relapse. Thus, dosage requirements remain highly individualized and some patients require frequent dosage changes.

Most certainly some patients who respond favorably to I.M. agents may not require additional neuroleptic medication. Others may be found to be suffering from affective disorders, and their treatment of choice will be antidepressive agents or lithium. Additional research should help document which patients should be continued on neuroleptics and to better establish guidelines for switchover to oral agents.

Another question requiring research is that of safety. The relative safety of haloperidol is well established (19). In general, adverse effects are related to dosage. The risks of treatment should be outweighed by the potential merits. According to the studies reviewed, I.M. haloperidol is well tolerated and does not involve serious complications. However, the longer term adverse effects and toxicity of the drug were not evaluated in these studies because of the rapid switchover to oral medication. Such data could be obtained only by maintaining patients for several days on injectable medication, a practice that is not normally clinically practical. Therefore, since adverse effects are related to dosage, the physician should use the least amount of medication necessary to provide therapeutic response.

Finally, the investigation of pharmacological effects has provided important leads into the biology of schizophrenia (20). Rapid neuroleptization may be of particular value here due to higher initial serum levels and rapid patient response.

Coercive Persuasion (Brainwashing), Religious Cults, and Deprogramming

BY J. THOMAS UNGERLEIDER, M.D., AND DAVID K. WELLISCH, PH.D.

Psychiatric interviews and psychological testing were conducted with 50 members or former members of a variety of religious cults who contacted the authors about the issue of deprogramming. The subjects were divided into four groups: cult members who feared deprogramming, those who had returned to the cult after deprogramming, ex-cult members who had left after deprogramming, and those who had left without deprogramming. There were significant differences between these groups on length of time in the cult, perception of and resistance toward the deprogramming experience, status of parental marriage, and who became a deprogrammer. No evidence of insanity or mental illness in the legal sense was found.

THE INFLUENCE of religious cults, or new religions, on young people and the recent spate of efforts to "deprogram" them have raised intriguing and disturbing questions for the medical, legal, and mental health professions, as well as for religious leaders and government authorities. Religious freedom and parental control, so central to American society, are crucial related issues. Deprogramming has recently received wide coverage in the mass media. The procedure is performed at the instigation of and financed by the parents. The deprogrammer forcibly removes the person who has reached the age of majority) from his cult or group and puts him through a series of procedures called deprogramming. These procedures vary widely and may range from gentle rap sessions to sleep deprivation and sensory overload, with marathon-type encounters that feature shouting, repetitious derogations of the cult, isolation of the person from former associates, moving the deprogramee from place to place within a period of days, and, occasionally, use of physical force in the event that he or she tries to leave or escape.

evised version of a paper presented at the 131st annual meeting of ie American Psychiatric Association, Atlanta, Ga., May 8–12, 978; received May 26, 1978; revised Sept. 15, 1978; accepted Oct. 7, 1978.

r. Ungerleider is Associate Professor of Psychiatry and Dr. Wellsch is Assistant Professor of Medical Psychology, University of alifornia at Los Angeles Medical Center, Neuropsychiatric Institute, 760 Westwood Plaza, Los Angeles, Calif. 90024.

The issue of group control and group influence over an individual's ideologic, political, or religious beliefs is not new. Concern over group domination and manipulation of individual belief systems peaked in the behavioral sciences after the Korean War, during which prisoners of war were purportedly brainwashed and influenced to accept Communist doctrine. Lifton (1), after intensive study of the Communist Chinese methods for mass ideological influence, suggested eight psychological themes as basic ingredients in "thought reform": 1) milieu control, 2) mystical manipulation, 3) demands for political and/or ideologic purity, 4) personal confession, 5) acceptance of basic group dogma as sacred, 6) constriction or "loading" of language into polarizing terms, 7) subordination of person to doctrine, and 8) dispensation of existence. Lifton theorized that a firm control over these eight variables would result in a process of "ideologic totalism."

Our purposes in this paper are 1) to report on certain psychosocial characteristics of 50 individuals who are or were members of several new religions, 2) to describe their ability to make sound legal decisions about their choice of lifestyle, and 3) to call attention to some of the problematic issues woven into the complicated patchwork of religious cults.

METHOD

As word spread of our interest, we were contacted by a variety of people on both sides of the issue of cults and deprogramming who asked us to evaluate members who had left cults, who had been taken from but later escaped and returned to cults, or who feared being taken from the cults for purposes of deprogramming. We examined these people without charge. We did indicate, however, that we would be willing, if asked, to give our findings in a court proceeding. However, this was never required. This became the motivation of many cult members to cooperate with us. Those who were no longer cult members cooperated mainly out of a desire to further knowledge in this area. It is important to note that we did not promise cult members that our findings would be positive or helpful to them should they be presented in court. We promised only to deliver the data, if asked, exactly as obtained, whether they indicated soundness of personality and intellect or deficits in these spheres.

Subjects

We examined subjects' status in relation to the groups rather than focusing on which cults they belonged to or had belonged to. The first group consisted of 22 subjects who feared deprogramming and remained in cults (concerned members). The second group consisted of 11 subjects who had been deprogrammed and had returned to their cults (returnees). The third group included 9 subjects who had been deprogrammed and had not returned to the cult (the nonreturnees); 6 of these 9 subjects had subsequently become deprogrammers. The fourth group consisted of 8 subjects who had left the cult of their own volition (voluntary ex-members). All subjects were voluntary and self-referred, and they received no monetary or other form of compensation. The subjects were tested in various locales in California and New York during their participation in the study.

Procedures

Both psychological and psychiatric data were gathered during one visit. Psychiatric data consisted of 1) a structured interview, which probed areas such as mental and physical health history, drug use history, family variables, experience in the group, and general motivational characteristics, and 2) a traditional mental status examination, which assessed affect, cognition, general psychological orientation, degree of insight, and social judgment.

Psychological data consisted of 1) the short form of the Weschler Adult Intelligence Scale, which correlates highly (r=.97) with the full-length form, 2) the Minnesota Multiphasic Personality Inventory (MMPI), 3) the Draw-a-Person test (not discussed in this paper), and 4) the Interpersonal Check List (ICL), developed by La Forge and Suczek (2). On the checklist all subjects were asked to rate the way they viewed themselves before and after they joined the group. The two main dimensions of dominance/submission and love/hate (affiliativeness/disaffiliativeness) were the ones considered in the study.

Statistical Analysis

The psychiatric interview data were sorted into categories, coded, and analyzed by the chi-square test with unequal cells. The psychological test data were analyzed by multivariate or one-way analysis of variance (ANOVA).

RESULTS

Structured Interview Data

Data analysis revealed that most of the interview variables did not significantly differentiate the groups. Nonsignificant variables included age, sex, marital status, religion of nuclear family, birth order, drug history, mental health history, educational level, and father's occupation.

However, some significant differences did emerge. The length of time in the cult was highly significant ($p \leq .0003$); 68% of the concerned members group and 91% of the returnees had been in the cult 1 year or more, while all of the nonreturnees had been in for less than 1 year. The voluntary ex-member group was more evenly spread across time intervals—38% had been in for less than 1 year and 62% for 1 year or more.

Perception of and resistance toward deprogramming significantly differentiated the groups ($p \leq .0001$). All subjects who had returned to the cult viewed their deprogramming experience as "not gentle" while 88% of those who did not return viewed it as "gentle." This is associated with physical resistance or nonresistance to the procedure; 63% of those in the returnee group physically resisted deprogramming, while only 11% of nonreturnees did so ($p \leq .0001$).

Status of parental marriage significantly differentiated the groups ($p \leq .03$). The rate of intact parental marriages was significantly higher for the concerned member (91%), returnee (82%), and nonreturnee groups (78%) than for the voluntary ex-member group (50%).

The issue of becoming a deprogrammer differed significantly between the groups ($p \leq .0001$): 88% of the nonreturnees but none of the subjects in the other groups became involved in deprogramming activities.

Mental Status Exam Data and WAIS

All persons tested were normal on all aspects of the mental status examination. The groups did not differ significantly on the verbal, performance, or overall IQ scores. The ranges of group means on the IQ were verbal, 103–114 (overall verbal mean=111); performance, 114–120 (overall performance mean=116); and overall, 115–119 (overall mean=117).

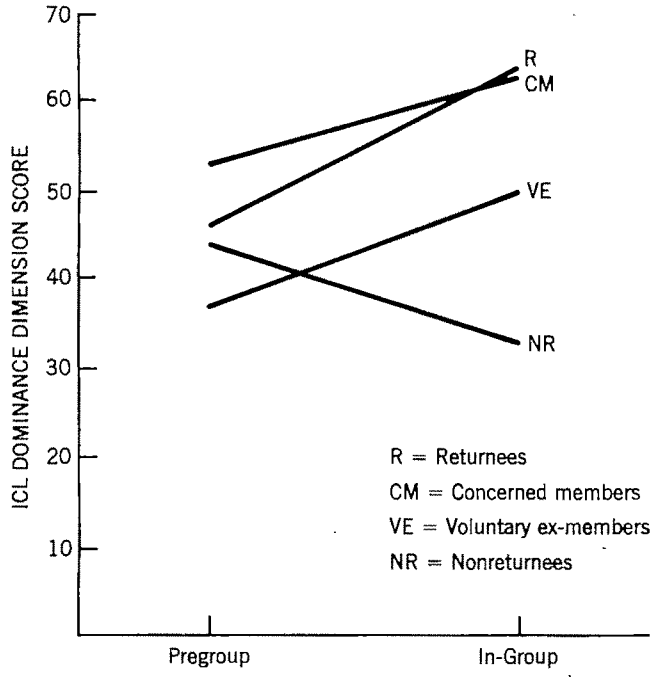
Interpersonal Check List Data

The group data on the ICL dominance/submission variable were analyzed by one-way ANOVA, and significant main effects of group status ($p \leq .02$) and subject's self-image (before versus in cult) ($p \leq .03$) were found. There was a strong but nonsignificant trend toward interaction of these main effects ($p \leq .08$) (see figure 1). The returnees and concerned members were closely paired, viewing themselves as having become highly dominant while in the cult, whereas the voluntary ex-members saw themselves as much less dominant while in the cult, and the nonreturnees indicated they had become frankly submissive during their cult membership.

The group data on the ICL love/hate variable (see figure 2), also analyzed by one-way ANOVA, revealed a significant main effect of subject's self-image ($p \leq .001$) and a Self-Image × Group Status interaction ($p \leq .04$). The nonreturnee, returnee, and concerned member groups viewed themselves as having become significantly more emotionally affiliative while in the cult, whereas the voluntary ex-members saw themselves as almost unchanged on this variable.

Scoring for these two variables ranges from 10 to 90

FIGURE 1
Pregroup and In-Group Mean Scores on ICL Dominance Dimension



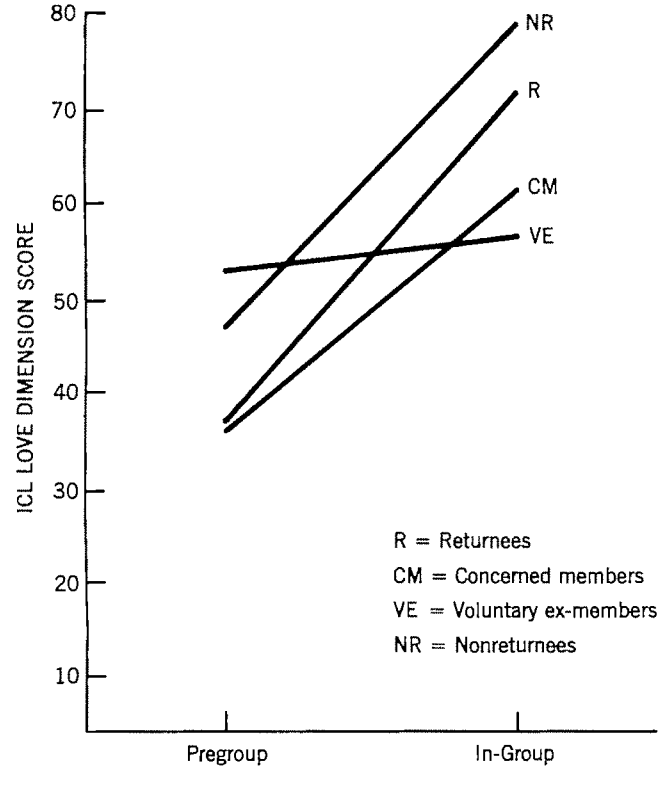


FIGURE 2
Pregroup and In-Group Mean Scores on the ICL Love Dimension

on the dominance/submission variable. Scores of 10–40 indicate a submissive interpersonal style, while scores of 60–90 indicate a dominant interpersonal style. Scores between 40 and 60 situationally reflect elements of both dominance and submissiveness. On the love/hate dimension, scores of 10–40 indicate a disaffiliative interpersonal style, while scores of 60–90 indicate an affiliative interpersonal style. Scores between 40 and 60 would situationally reflect elements of both affiliativeness and disaffiliativeness.

MMPI Data

The MMPI data were dealt with by collapsing the four groups into two: the concerned member and returnee groups were labeled "in" and the nonreturnee and voluntary ex-members were labeled "out." Both groups fell within the grossly normal range: the out group had peaks on scales 4 and 3 (Psychopathic-Deviancy and Hysteria), while the in group had peaks on scales 8 and 6 (Schizophrenia and Paranoia). It should be noted that the in group had an elevation on the Lie scale, which indicates 1) an intentional attempt to make a good impression and to deny faults ("fake good"), and 2) neurotic characteristics, including the prominent use of the defenses of repression and denial, coupled with a generalized lack of insight. Thus, it is likely that many of the in group's subscales would have been elevated had they not consciously skewed their responses.

The in group scored significantly higher on the Lie scale ($p \leq .02$). The out group scored significantly higher on the Paranoia scale ($p \leq .05$) and the Schizophrenia scale, with a strong but nonsignificant trend ($p \leq .09$) on the Psychasthenia scale.

Five research subscales were assessed between the two groups. The in group was significantly higher on the Psychopathic-Deviancy subscale 1 (anger at family members) ($p \leq .007$), and on Overcontrolled Hostility ($p \leq .05$), a subscale developed by Megargee (3, 4). A strong but nonsignificant trend ($p \leq .08$) emerged for the in group to score higher on the Alcoholism Vulnerability subscale developed by MacAndrew (5).

DISCUSSION

No data emerged from intellectual, personality, or mental status testing to suggest that any of these subjects are unable or even limited in their ability to make sound judgments and legal decisions as related to their persons and property. Most clear from our data was the finding that forcible removal of individuals from any group to which they have belonged for more than 12 months is exceedingly difficult.

Data from the MMPI delineate substantial intrapsychic and interpersonal differences between current cult members and those who have left. Subjects who were still cult members indicated difficulty with impulses in several areas and attendant superego deficits, such that the cults appear to serve as externalized superego substitutes. These difficulties were particularly strong in the area of hostility management. The trend toward concern over impulsive and dependent

use of alcohol and other drugs might be viewed as a reflection of frustrated oral dependency needs.

Test results indicate these impulses were dealt with by overconventionalism, repression, denial, and lack of insight. All of these can easily be seen to be incorporated into a lifestyle based within the cults. Those subjects who had left the cults were not free of psychological difficulties, and for this group social alienation, emotional alienation, and lack of ego mastery were dominant themes. We did not focus extensively on the nuclear family system of the cult member. This variable is a logical and critical next step in research on the core motivational aspects of the young religious cult member.

COMMENT

The groups all emerged as intellectually capable on testing. They revealed clinically an intellectual and philosophical bent that resembles what Lifton has termed "strong ideological hunger," regardless of their status in relation to the cult. These cults appear to provide, at least for a time, nourishment for these ideologic hungers as well as relief from the internal turmoil of ambivalence.

The ICL data indicated that those who tended to drop out without outside intervention appeared to have different motivations for joining the cults than did those who left the cults via outside intervention (deprogramming). It appeared that for those who left on their own, the needs were less intense for a safe, structured, predictable environment which would permit relatively conflict-free emotional affiliation with others. The other three groups appeared to join these religious cults, in part, out of intense needs for such structured opportunities to make emotional connections with others, which they had viewed as highly difficult before they joined the groups. The data did show, however, that the provision of a safe milieu for affiliation with others is not enough to hold all those who join cults. For those who left after deprogramming, the attraction of affiliation appeared to be counterbalanced by a rejection of the group based at least in part on a negative reaction to a sense of being dominated and forced into an unendurably submissive role. The fact that those who remained in the cults did not feel dominated and actually felt dominant may be partially explained by a cognitive-dissonance model. Their perceptions appear to differ from the reality that all of the cults function on a hierarchical model of power. This structure, by definition, excludes most members from major decisions or from positions of dominance.

The basis or etiology of the difficulties with hostility present an enigma not readily answerable by this study. There is some evidence, however, that points to the existence of hostility prior to joining the cults. The finding that those in the cults experienced hostile feelings toward their families far in excess of those who had left the cults is noteworthy. It is highly probable that the threat or actual experience of being deprogrammed increased the hostility. It would seem unlikely that the hostility stems entirely from the deprogramming issue and is totally unrelated to the pre-cult family process. It also seems equally unlikely that the overcontrolled, internalized hostility would exist only in regard to the family. The data suggest that the cult members might also feel hostile toward other authority figures, including cult leaders. The conscious realization or experience of hostility toward cult leaders would very likely be heavily repressed, or denied. Alternatively, this denied or repressed hostility might be projected onto figures outside the cults.

Antipsychotic Effects of Lithium in Schizophrenia

BY PAUL E. ALEXANDER, M.D., DANIEL P. VAN KAMMEN, M.D.,
AND WILLIAM E. BUNNEY, JR., M.D.

The lithium carbonate therapy of 13 psychotic schizophrenic patients was evaluated in a placebo-controlled three-week study that was double-blind. Seven of the 13 patients were less psychotic while receiving lithium; 4 of these 7 patients relapsed after lithium withdrawal. Patients who improved during the third week on lithium could be differentiated from nonresponders on the basis of their improvement during the first week. Clinical factors such as diagnosis, prognosis, and symptoms failed to predict responders from nonresponders. To the authors' knowledge, this is the first controlled study to yield positive results with schizophrenic patients treated with lithium alone.

LITHIUM HAS proven efficacy in the treatment (1-4) and prophylaxis (5-9) of mania and depression, but it is generally believed to be ineffective in the treatment of schizophrenia (10-14). The history of lithium trials in schizophrenia began with Cade's classic paper (15) introducing lithium to psychiatry. He found that 3 of 6 patients with chronic dementia praecox who were treated with lithium showed a reduction in excitement; this work led to further trials, first with excited schizophrenic patients (16, 17) and later with excited schizoaffective patients (18-20). In all of these anecdotal reports some patients were found to improve on lithium.

Two controlled studies (14, 21) with excited schizoaffective patients yielded conflicting results. The first report (14) indicated that 6 of 11 patients worsened on lithium, with 5 showing organic brain syndromes; 4 other patients remitted or showed some improvement. High lithium blood levels, which ranged from 1.0 to 2.5 mEq/liter, probably had a role in the organic side effects. In a larger collaborative study with excited schizo-affective patients (21), lithium produced as marked an improvement in affective and psychotic behavior as chlorpromazine did in mildly active patients. Equivalent results with lithium and chlorpromazine were also found in the group of highly active patients who completed the lithium trial, but 35% of these patients could not complete the trial because of behavior problems. One patient terminated due to toxic confusion.

To our knowledge, lithium prophylaxis with schizoaffective schizophrenic patients has been reported in only one study, which was large, collaborative, and uncontrolled (7). The frequency of psychotic episodes was significantly reduced in the lithium treatment group.

Clinical trials of lithium in patients with schizophrenic subtypes other than schizo-affective have yielded good results (22, 23). One placebo-controlled report (22) found that lithium combined with phenothiazines was more effective than phenothiazines alone in chronic schizophrenic patients. In an anecdotal report, atypical psychoses with paranoid, confusional, and periodic features were responsive to lithium (23).

We have found only one previous double-blind controlled study of lithium therapy with schizophrenic patients (13). As a group, the 11 patients treated with lithium in that study did not respond favorably, and 6 of them worsened, with central nervous system toxicity, despite blood levels of less than 1.3 mEq/liter.

One of the difficulties in reviewing the literature on lithium involves the diagnostic criteria for schizophrenia. Spitzer and associates' Research Diagnostic Criteria (RDC) for typical schizophrenia and schizo-affective schizophrenia have been developed recently (24) but have not been used in controlled lithium trials. Similarly, "good prognosis schizophrenia" (25) is a clearly defined subgroup that is indistinguishable in several prognostic and genetic characteristics from manic-depression; lithium has not been studied in a group of patients defined in this manner.

In this study the antipsychotic properties of lithium were examined in a double-blind placebo-controlled study with psychotic schizophrenic patients.

Revised version of a paper presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977. Received March 24, 1978; accepted Oct. 13, 1978.

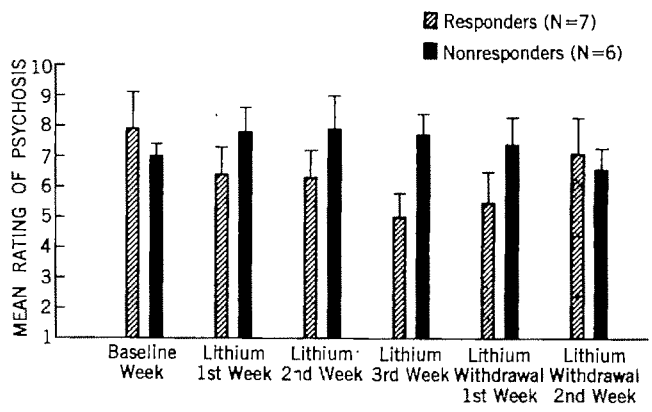
[b]Clinical improvement of more than 1.5 points during the third week on lithium compared with the drug-free week, with relapse after lithium withdrawal.
[c]Clinical improvement of more than 1.5 points during the third week on lithium compared with the drug-free week, without relapse after lithium withdrawal.

METHOD

Thirteen schizophrenic patients (7 women and 6 men) participated in the study. They ranged in age from 19 to 53 years old, with a mean age of 26. They were voluntarily hospitalized on a clinical research unit of the National Institute of Mental Health and gave written informed consent for this study.

The clinical diagnosis of schizophrenia, including *DSM-II* subtypes (26), was made by consensus of 3 psychiatrists familiar with the patient. Each patient was also evaluated by his or her therapist according to the 1975 edition of the RDC (24) (patients' therapists were not directly involved in the study). Furthermore, patients had to have four or more differential symptoms from the International Pilot Study of Schizophrenia (27).



Patients were drug-free prior to the lithium trial; they took placebo capsules for at least 1 week before and 2 weeks after the 3-week trial of lithium.

Nursing staff, blind to drug, rated patients daily for psychosis using the modified 15-point Bunney-Hamburg Global Rating Scale (28).

Lithium carbonate was administered orally in divided doses, starting with a loading dose of 1800 mg for the first 3 days, followed by a lowering of the dose based on serum levels, side effects, and the clinical judgment of the physician responsible for medication. The dose during the third week averaged 1600 mg/day (range=1200 to 2800 mg/day). Serum levels during the third week averaged 0.9 mEq/liter (range=0.7 to 1.2 mEq/liter).

The mean ratings for the third week of lithium therapy were compared with those of the week prior to lithium as well as with those of the second week after withdrawal. Baseline ratings for psychosis ranged from 4.1 to 11.5 (mean=7.5). Responders showed a mean rating improvement of at least 1.5 points during the third week on lithium.

FIGURE 1
Mean Group Ratings of Psychosis for Lithium Responders and Nonresponders

The *DSM-II* schizophrenic subtypes of the patients were as follows: schizo-affective schizophrenia (N=3), acute (N=3), paranoid (N=1), catatonic (N=3), and chronic undifferentiated schizophrenia (N=3). Based on the RDC system, 5 patients were schizophrenic; 3 were schizo-affective, manic type; and 5 were schizo-affective, depressed type.

Patients were also evaluated by the following: age of onset, Phillips scale (29), Vaillant criteria (30), Schneiderian first-rank symptoms (31), the Modified Prognostic Scale (32), and the Taylor-Abrams prognostic criteria (25). The Modified Prognostic Scale consists of the following 4 items that Strauss and Carpenter found to be predictive of outcome: previous hospitalization, unemployment, poor social relations, and flattened affect. The Taylor-Abrams modification of the Robins and Guze criteria (33) was used with the original definition of sudden onset as less than 6 months.

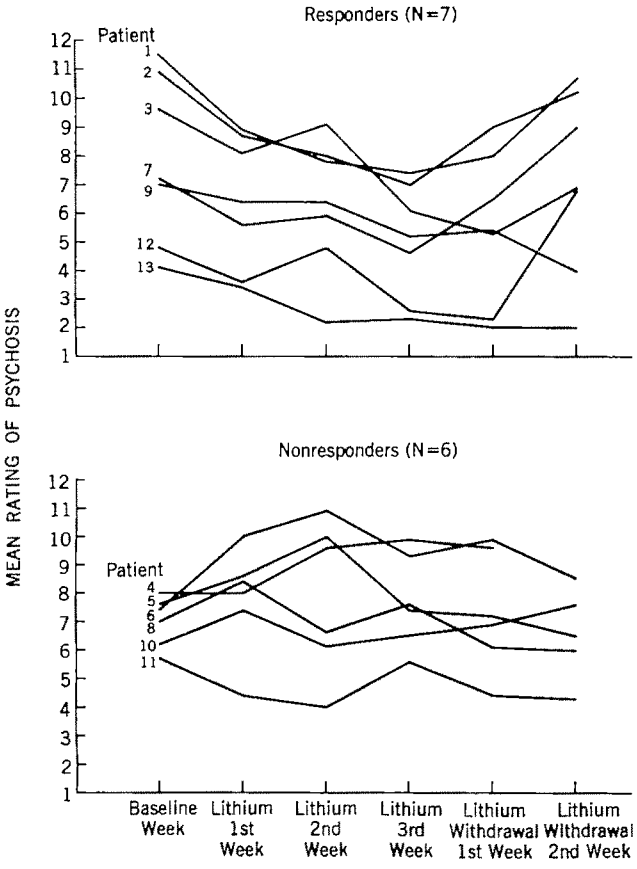
RESULTS

Of the 13 patients in the trial, 7 showed clinical improvement during the third week on lithium (table 1). Four of these 7 responders relapsed within 2 weeks after lithium withdrawal.

The mean psychosis ratings of responders are compared with the ratings of nonresponders in figure 1. The means of the 2 groups were not significantly different during the drug-free baseline week. On lithium the mean psychosis ratings of responders decreased during the first week and decreased further during the third week. The rating during the third week on lithium improved from a baseline mean of 7.9 to a mean of 5.0. After lithium withdrawal the responders showed a progressive deterioration to a mean rating of 7.1. Nonresponders showed minimal changes during lithium treatment and withdrawal.

Figure 1 presents the individual data for both responders and nonresponders. Responders included pa-

FIGURE 2
Mean Individual Ratings of Psychosis for Lithium Responders and Nonresponders



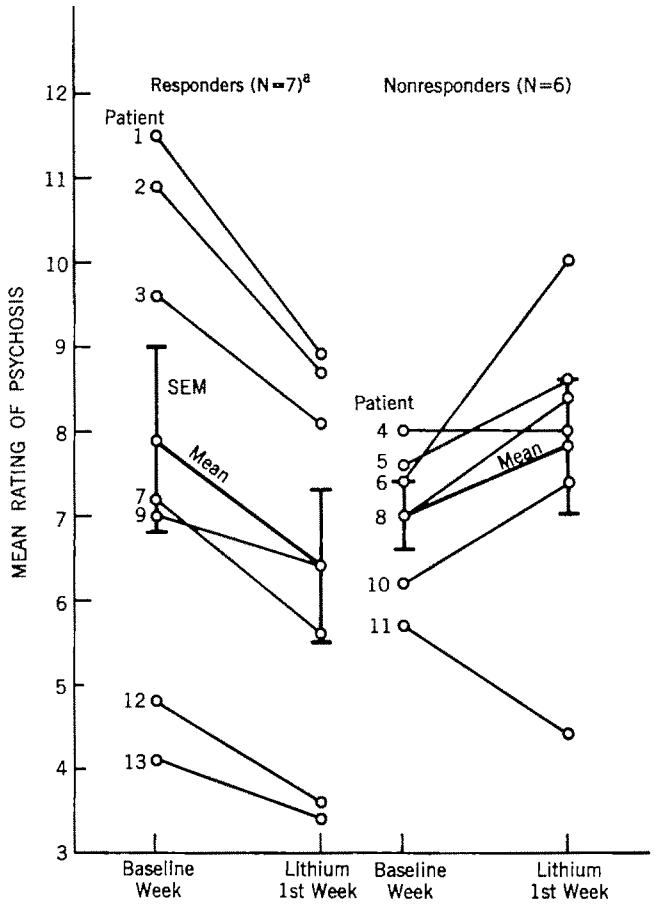


FIGURE 3
Mean Ratings of Psychosis During the First Week for Lithium Responders and Nonresponders

[a]Lithium responders improved significantly more during the first week ($p<.005$).

tients with the following *DSM-II* diagnoses: schizophrenia, schizo-affective, chronic undifferentiated, paranoid, catatonic, and acute schizophrenic episode. The RDC diagnoses of the responders included schizophrenia, schizo-affective, manic type, and schizo-affective, depressed type (table 1).

The data in figure 2 suggest that improvement occurred in responders within the first week. This effect is shown in more detail in figure 3. All responders showed some improvement during the first week from a baseline mean rating of 7.9 to 6.4. Only 1 of 6 nonresponders showed improvement during the first week. Differences between the two groups in improvement during the first week were found to be highly significant ($p<.005$).

Responders to lithium were compared with nonresponders on the basis of several criteria (see table 2). Both groups were similar in all factors examined, including age of onset, prognostic scales, and symptoms of schizophrenia.

DISCUSSION

Psychotic patients of diverse schizophrenic subtypes participated in a double-blind placebo-controlled trial of lithium carbonate. Slightly more than half of the patients showed clinical improvement in psychosis during lithium treatment. A majority of these responders relapsed within two weeks after lithium withdrawal. The improvement was modest (mean rating change of 2.9 on the Bunney-Hamburg scale), and no patients showed a complete remission of psychotic symptoms. However, the study provides evidence that lithium has antipsychotic as well as antimanic and antidepressant properties.

To our knowledge, this is the first controlled study to yield positive results with schizophrenic patients treated with lithium alone. The findings confirm anecdotal reports of lithium efficacy in schizophrenia (23, 34) but are at variance with the only other controlled lithium study of acutely psychotic patients. In that study Shopsin and associates (13) reported no improvement in any patients and deterioration in about half of the sample. In contrast, in the present study lithium did not appear to aggravate psychotic symptoms. The only patients whose psychosis ratings were higher during the third week on lithium (patients 5 and

TABLE 2
Similarities Between Responders and Nonresponders to Lithium

6) were not affected by lithium withdrawal, suggesting that their clinical changes were independent of lithium. Neurotoxicity, which was frequent in the previous study, was not observed in any patients in our study. The most likely explanation for the difference in the two studies is the patient population. Quitkin and associates (34) have suggested that patients in the earlier study may have been "asocial schizophrenics" who had central nervous system dysfunction and were prone to toxicity to any psychotic agent. Other lithium studies with schizophrenic patients have not reported an unusual sensitivity to lithium toxicity (3, 22, 23). Our data thus suggest that schizophrenic patients are neither worsened by lithium nor more sensitive to neurotoxicity.

The findings suggest that the clinical efficacy of lithium is not disease-specific for manic-depressive illness, as others have suggested (12, 14, 35). The patients in the study were diagnosed as schizophrenic by 3 psychiatrists and met several criteria prior to the lithium trial. Schizophrenic features predominated over affective symptoms in patients who met the RDC criteria for schizo-affective illness, and 5 of 8 patients diagnosed as schizo-affective by RDC criteria carried diagnoses other than schizo-affective based on *DSM-II* criteria.

In contrast to the generally slow improvement with neuroleptic drugs, the data suggest that lithium responders show early signs of improvement in the first week (figure 3). All 7 responders showed improvement in ratings in the first week on lithium; 5 of 6 nonresponders showed a worsening or no change during the first week. This rapid improvement suggests the feasibility of performing relatively short clinical trials of lithium.

The magnitude of the responders' improvement in the first week was also examined in relation to the magnitude of the improvement during the third week on lithium. Linear regression analysis of the improvements during these two periods was found to be directly proportional ($r=0.94$, $p<.01$). That is, the patients with the greatest improvement during the first week showed the greatest improvement during the third week relative to the baseline week. This preliminary finding suggests that the response within the first week may predict later outcome on lithium.

The response during the first week was the only predictive factor found in the study. The responders and nonresponders showed no prospective clinical differences that could be detected in our study. In fact, the similarities between the two groups were striking (see table 2).

A previous study of lithium efficacy in patients with primary affective illness (36) suggested that serum calcium (Ca) and magnesium (Mg) were of predictive value. In that study, a high ratio of drug-free Ca/Mg was predictive of positive outcome, as were increases in Ca and Mg during the first 5 days of treatment. These measures were also used in our study. Serum Ca and Mg, drawn during the baseline drug-free week at 8:00 a.m., were measured by atomic absorption spectroscopy (37) at the clinical chemistry laboratory of the NIH clinical center. Our data showed a trend level of significance ($p=.08$, Fisher's exact test) for the drug-free ratio Ca/Mg as a predictor of responsiveness to lithium in schizophrenic patients. Responders had a higher ratio than nonresponders during the drug-free periods ($2.70\pm.05$ mEq/liter versus $2.60\pm.05$ mEq/liter). The increase in Ca and Mg during the first week was found in the large majority of patients, regardless of responsiveness (10 of 11 patients had an increase in Mg and 11 of 12 patients had an increase in Ca). The increase during the first week for all patients on lithium compared with the drug-free week was significant for both Ca ($p<.005$) and Mg ($p<.025$) by paired t tests. The findings thus support prediction by drug-free Ca/Mg but not by the increase in electrolyte values during the first week.

We urge caution in applying our results to clinical practice. The possible clinical usefulness of lithium in schizophrenia needs to be evaluated in the context of the preliminary nature of our findings and the well-established efficacy of neuroleptic drugs. The current study involved a small number of patients treated with lithium for 3 weeks. It is important to emphasize that, although lithium had antipsychotic effects, it did not lead to a complete remission of symptoms in any patients in a manner similar to optimal neuroleptic response. Lithium has never been shown to be more effective than neuroleptics in treating schizophrenic patients as a group. Clearly, neuroleptics remain the medication of choice for schizophrenia. However, lithium may serve as an alternative medication for 3 groups of patients: those who do not respond to neuroleptics, those who cannot tolerate neuroleptic side effects, and those with medical conditions that contraindicate the use of neuroleptics.

Further controlled clinical trials of lithium in the treatment of schizophrenia are indicated.

Parental Criminality and Medical Histories of Delinquent Children

BY DOROTHY OTNOW LEWIS, M.D., SHELLEY S. SHANOK, M.P.H., AND DAVID A. BALLA, PH.D.

In clinical practice the authors observed that many of the delinquent children of psychiatrically impaired and/or criminal parents had remarkably adverse health histories. To test their clinical impression they systematically compared the medical histories of 20 delinquent children with criminal parents and 85 delinquent children with less obviously maladapted parents. They found a strong association between paternal criminality and serious medical problems in these delinquent children. On the basis of this finding the authors suggest that the behavioral manifestations resulting from such physical illness or neglect, although they appear genetic in nature, may reflect the physical and psychological consequences of parental neglect and/or battering.

THE PURPOSE of this paper is threefold: 1) to report the differences in medical histories between delinquent children with criminal parents and delinquent children with noncriminal parents, 2) to document the especially strong association between paternal criminality and serious medical problems in delinquent children, and 3) to explore some of the psychological, behavioral, and physical implications of these findings. In a previous study (1) we reported more serious and more numerous medical problems in a sample of delinquent children compared with a matched sample of nondelinquent children. We have also reported an association between criminality and serious psychopathology in the parents of delinquent children (2, 3). We wondered whether differences existed within the delinquent population itself between the medical histories of children with criminal parents and children with less overtly maladapted parents.

Received Nov. 14, 1977; revised Jan. 16, 1978; accepted March 2, 1978.

Dr. Lewis is Associate Clinical Professor of Psychiatry, Ms. Shanok is Associate in Research, and Dr. Balla is Associate Professor, Child Study Center, Yale University, 333 Cedar St., New Haven, Conn. 06510. Dr. Balla is also Associate Professor, Department of Psychology, Yale University.

This study was supported by grant 7750512 from the Ford Foundation and grant LEAA 76AE418003X from the State of Connecticut.

THE LITERATURE

We consider parental criminality not only a measure of social maladaptation but also an index of parental psychopathology that is especially hazardous to the development of offspring. There is strong evidence in the literature that criminality and psychiatric disorder are often closely related.

Penrose (4) noted that before World War II European countries with large prison populations had small mental hospital populations and vice versa. Gunn and associates (5, 6) reported that approximately one-third of the prisoners they interviewed had abnormalities in their mental state at the time of the interview. Our own studies of the parents of delinquent children (2, 3) indicated an association between parental criminality and parental psychopathology.

Most studies of parents and children have focused on the relationships between the psychiatric states of children and parental psychiatric or physical illness rather than parental criminality. Rutter (7) found psychiatric illness to be three times as common in the parents of children in a psychiatric clinic as in the parents of children in a pediatric or dental clinic. However, Sterne (8) reported that parental psychiatric illness was less closely associated than parental physical illness with children's serious antisocial behaviors. Waring and Ricks (9) reported an association between paternal and maternal psychopathology and schizophrenia in children.

Some investigators have focused on differences between the effects on children of paternal compared with maternal psychopathology. Wolff and Acton (10) reported maternal neurosis to be more closely related than paternal neurosis to children's emotional disorders. West (11) reported an association between maternal instability and serious behavior problems in male children. Mednick and Schulsinger (12) found significantly more mental illness requiring hospitalization in fathers of the psychiatrically disturbed offspring of schizophrenic mothers than in fathers of the well-functioning offspring of schizophrenic mothers.

Landau and her colleagues (13) conducted one of the few studies focusing on the physical as well as the mental states of offspring of seriously disturbed parents. They reported not only more undisciplined behavior at home and at school, more physical aggression against peers, and more delinquency in the off-

0002-953X/79/03/0288/05/$00.50 © 1979 American Psychiatric Association

spring of psychotic parents but also poorer health histories in the children of psychotic parents compared with those of nonpsychotic parents. Although behavioral problems in the children of psychiatrically disturbed parents have been noted in many offspring studies, rarely has there been a focus specifically on documented delinquency. Furthermore, to the best of our knowledge, the question of parental criminality and the medical status of delinquent offspring has not been addressed.

Studies of the offspring of antisocial parents have, for the most part, focused on the transmission of deviant behaviors rather than on medical histories. They have been predominantly psychodynamic (14), genetic (12, 15), or sociological (16–18). Health problems of the offspring of antisocial parents have generally been ignored. The few studies concerned with the physical health of delinquent children have been inconclusive (19, 20), and those indicating an association between poor physical health and delinquency have not usually included studies of the parents of the delinquent children.

CLINICAL OBSERVATIONS

Our own investigation of the possible association of severe parental maladaptation and serious medical problems in delinquent children sprang from the clinical observation that many of the delinquent children of psychiatrically impaired and/or criminal parents had remarkably adverse health histories. For example, one psychotic mother of a seriously delinquent boy had broken all of his fingers at different times. This mother was known to have been psychiatrically hospitalized. Another mother of a depressed epileptic girl had frequently thrown the child around by the hair and banged the child's head against the wall. One psychotic father, on discharge from a psychiatric hospital, threw his infant son across the room like a basketball. At other times he burned his children with cigarette butts.

Many children of criminal parents have suffered serious injury not directly inflicted by the criminal parent. One child who fell from a second-story window had a father who had been jailed for shooting off guns in the house. Another child who had fallen from a third-floor window had a violent father who had been incarcerated as a youngster.

We also found that the delinquent children of seriously disturbed parents often made many visits to hospitals for a variety of apparently minor illnesses as well as for accidents and injuries. Clinically, it looked as though the delinquent children of disturbed, violent parents had especially adverse medical histories.

These kinds of clinical observations led us to undertake a more systematic comparative study of the medical histories of delinquent children with criminal parents and the medical histories of delinquent children with less obviously maladaptive parents.

METHOD

Subjects

We selected a random sample of 109 delinquent children from the total number of referrals to a juvenile court in the early 1970s. A list of the name, birthdate, race, and place of residence of the child and the child's parents was compiled. The medical records of 4 of the 109 children were unavailable.

Measures of Parental Criminality

The list of parents was cross-checked with the central files of the state police to determine documented parental criminality. Issues of case loss arising in such research strategy have been discussed extensively elsewhere (2, 21). Twenty of the 105 children whose medical records were available had criminal parents; 85 did not.

Measures of Medical Status

We evaluated the medical history of each child in the study on the basis of an extensive review of his or her hospital record in the major general hospital serving the area. Approximately 95% of the children had used this hospital. Few of the children in the sample (about 25%) had used the one other smaller hospital serving the area. Furthermore, data from that hospital could not be retrieved with accuracy at the time of the study.

The decision to limit our study to one main large general hospital raises issues of case loss. Although it would have been desirable to interview parents and children regarding medical events, such personal contact was prohibited by the court. There is evidence that data based on parental recall are often inaccurate (22). Data from other public and private medical facilities were unavailable because of issues of confidentiality. However, the hospital selected tended to be used by the less affluent in the community as a source of primary care. In fact, the hospital subsequently developed a primary care service to meet the needs of the many patients who used the clinics and emergency room in this way. Furthermore, serious accidents and illnesses would most likely have been referred to this hospital, making hospital use for such problems an especially accurate reflection of incidence.

The date and the reason for each hospital visit were recorded. These data were later categorized as follows: total number of visits through age 16, total number of visits before age 12, total number of visits before age 4, total number of accidents and injuries through age 16 and before ages 12 and 4, head or face injuries through age 16 and before ages 12 and 4; and respiratory infections through age 16 and before ages 12 and 4. We also took note of any reference to child abuse in the medical record.

The number of and reasons for hospital visits through age 16 provided an overall picture of a child's medical status. Our interest in hospital contacts before

age 4 reflected the consensus in the literature that early physical illness or trauma may have important consequences for future adaptation (23-25). Our study of patterns of hospital use before age 12 sprang from the fact that most delinquent acts occur between ages 12 and 16. Thus, early recognition of certain health patterns and family constellations associated with delinquency might have implications for early intervention and, we hoped, delinquency prevention.

FINDINGS

The mean number of hospital contacts and the nature of hospital contacts over time for the delinquent offspring of criminal parents and for the delinquent offspring of noncriminal parents are presented in table 1. As this table shows, the delinquent children of criminal parents had more hospital visits than did those of noncriminal parents before age 4, before age 12, and through age 16. Of special interest is the fact that the children of criminal parents had significantly more accidents and injuries before age 4 than did children of noncriminal parents. There was a tendency for child abuse to be noted more frequently in the records of delinquent children of criminal parents (20% of criminal parents had an abused child compared with 5% of noncriminal parents (χ^2=2.513, p=.113, Yates correction). Paternal criminality contributed most strongly to this difference (20% of criminal fathers had an abused child compared with 6.7% of criminal mothers).

The mean number and the nature of hospital contacts for children of criminal and noncriminal fathers are presented in table 2. The delinquent children of

FIGURE 1
Mean Number of Hospital Visits of 20 Delinquent Children with Criminal Parents, 85 Delinquent Children with Noncriminal Parents, and 109 Nondelinquent Children

criminal fathers had more hospital visits before ages 4 and 12 and through age 16 than did those of noncriminal fathers. Further, the children of criminal fathers had more accidents and injuries, head injuries, and (at a borderline level of significance) more respiratory illnesses before age 4 than did the children of noncriminal fathers. This same pattern of findings was evident before age 12.

In contrast to these findings, there were no significant differences in the medical histories of the delinquent children of criminal mothers compared with those of noncriminal mothers. When the medical histories of the 15 children of criminal fathers were compared with those of the 5 children of criminal mothers, no differences reached conventional levels of statistical significance because of the small sample sizes. Nevertheless, on each of the variables investigated, the children of criminal fathers had more adverse medical histories than did those of criminal mothers.

Using data from our previous study comparing the medical histories of delinquent and demographically similar nondelinquent children (1), we were able to compare the medical histories of delinquent children who had criminal parents, delinquent children who had noncriminal parents, and nondelinquent children. We found that although delinquent children had more serious medical histories than did nondelinquent children, delinquent children with criminal parents were at greatest medical risk. Paternal criminality contributed most heavily to the differences (see figure 1).

DISCUSSION

Clearly, the delinquent children of criminal parents in this study had more adverse medical histories than did the delinquent children of noncriminal parents. Whatever the measure—number of hospital contacts or nature of hospital contacts—the delinquent children of criminal parents fared extremely badly.

Among the delinquent children of criminal parents, those who suffered most from a medical point of view were the children of criminal fathers. The differences in medical histories between the children of criminal fathers and those of noncriminal fathers were most striking before the age of 4. This finding is particularly alarming because it indicates that physical trauma and medical illness occurred in the lives of these children at a crucial stage of development, when the CNS is growing rapidly. The effects of injury at this time are likely to have a lasting influence on a child's adaptation to school, peers, and society in general. Such CNS injury is often associated with hyperactivity, perceptual-motor disorders, and impulsivity, factors notable in the histories of many delinquent children (2).

Investigators who have observed an association between parental antisocial behavior and children's social deviance have looked primarily to psychodynamic and social learning theory (i.e., modeling) for explanations. Our clinical work suggests several other ways in which paternal criminality may affect both the adverse medical history and the delinquent behaviors of the children of criminals. First, many of the fathers with criminal records in our study were known to have severely beaten and/or tortured their children, causing CNS damage. The uncontrolled behaviors of many of these fathers (e.g., shooting guns out windows, driving recklessly while drunk) encouraged similar recklessness in their children, who then indulged in extremely dangerous behaviors resulting in further injury. Thus, the effects of modeling have physical correlates.

The children of criminal fathers, if not battered, are often neglected. These fathers, sometimes by choice, sometimes as a result of incarceration, are often not present in the home at all. We have documented the tendency of criminal fathers of delinquents to marry women who have been psychiatrically treated and/or hospitalized (2, 3). Therefore, when a criminal father is not in the home, his children are often left in the care of a seriously disturbed mother. Without adequate

nurturance and protection, these children are subject to many accidents, injuries, and illnesses. Of course, battering by distraught, overwhelmed, seriously psychiatrically impaired mothers is also a common finding in the histories of delinquent children.

Along with the prevailing psychodynamic and social learning theories of delinquency there has been a resurgence of interest in the possible genetic transmission of deviance (26–28). We would suggest that the transmission of impulsivity and serious antisocial behavior from father to son may have yet another explanation. The behavioral manifestations resulting from physical abuse or neglect may appear at first glance to be genetic in nature; in actuality they may reflect the consequences of parentally influenced injury

In summary, our clinical and epidemiological findings suggest that one of the ways in which paternal criminality affects children's deviant behaviors is through physical abuse or neglect that results in physical injury. This physical trauma, especially to the CNS at an early age, impedes a child's ability to perceive accurately, make sound judgments, and control impulses.

Schizophrenic Thought Disorders: Bizarre Associations and Intermingling

BY MARTIN HARROW, PH.D., AND MEL PROSEN, M.D.

The authors assessed bizarre verbalizations elicited from 37 schizophrenic and 16 nonschizophrenic patients. Interviews with subjects indicated that much bizarre schizophrenic language results from patients intermingling material from past and current experiences into their verbalizations. This intermingled material comes from many different problem areas rather than one central emotional complex. It does not arise from emotional overresponsiveness, overinvolved thinking, or delusional ideation. Two factors hypothesized as responsible for bizarre schizophrenic language are the schizophrenic's monitoring problems and difficulty maintaining perspective about his own behavior.

BIZARRE AND DISORDERED THINKING are considered central features in schizophrenia (1-7). At present, their cause is unknown. New techniques are needed to study more directly what factors influence or lead to disordered thinking. We have developed one such technique and have obtained results about intermingling, a factor that may play a role in determining disordered language in schizophrenia.

In recent research, we have explored a formulation about the importance of intermingling in disordered language (8, 9). This formulation was based in part on previous findings of a strong relationship between overpersonalized responses and bizarre verbalizations (10). According to our hypothesis, one overt factor that leads to schizophrenic patients' disordered verbalizations is an intermingling into their language (and possibly into their thinking) of material from their past or current experience (8). We believe intermingling and other types of disordered language are influenced by a difficulty of the schizophrenic in maintaining perspective about, and monitoring, his own language and behavior such that he does not fully recognize when he is inappropriate (11).

In recent research we found positive evidence about the presence of intermingling as a factor in disordered language (8, 9). However, this research was based on a small sample and lacked a control group of nonschizophrenics. The present research had several goals. The first was to investigate intermingling in a larger sample and to compare findings with those from a control sample of nonschizophrenics. Second, we wished to use our technique to explore other factors that might influence intermingling or disordered thinking.

The specific questions on which we will focus in the present report are as follows:

1. Do nonschizophrenics' strange verbalizations reflect intermingling, as we found to be the case for many schizophrenics?
2. Does each schizophrenic's intermingling involve material from one central area of concern, or emotional "complex," or does it represent overinvolvement in a variety of different topics?
3. Does the schizophrenic's intermingling represent a tendency toward overelaborate verbalizations or overinvolved thinking?
4. Does the schizophrenic's intermingling represent interference with language by strong emotional reactions or emotional overresponsivity to the material with which he or she is dealing?
5. Does the intermingling reflect delusional or paranoid material that influences thinking?

METHOD

Sample

The subjects were 53 psychiatric inpatients (37 relatively young schizophrenics and 16 nonschizophrenics) from a multidisciplinary research project on schizophrenia (8, 12-14). The schizophrenic sample included 10 paranoid schizophrenics and 27 schizophrenics whose most prominent symptoms were not primarily paranoid. These patients also met the criteria for a schizophrenic diagnosis on the New Haven Schizophrenia Index (15). The nonschizophrenic

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977; received May 18, 1977; revised Sept. 25, 1978; accepted Oct. 18, 1978.

UNIVERSITY OF ILLINOIS LIBRARY

sample consisted of 7 patients with affective disorders (5 depressed and 2 manic) and 9 patients with severe personality disorders. Only 3 of the 16 nonschizophrenic patients (the 2 manic patients and 1 depressive) showed strong evidence of psychotic thinking.

The mean age of 32 males and 21 females was 22.9 years. Almost all of the schizophrenics (91%) were taking phenothiazines or phenothiazine-like medications (e.g., haloperidol) at the time of assessment. The mean educational level of the sample was 12.4 years. The mean raw score on the WAIS Information Scale was 16.2, which falls within the average range of intelligence (16). There were no significant differences between the schizophrenic and nonschizophrenic samples on age, education, or intelligence.

Data Collection and Ratings of Intermingling

The overall research plan, which has been described more fully in previous reports (8, 9), involved three stages: 1) eliciting bizarre responses from each patient, 2) interviewing each patient about the reasons for his bizarre responses, and 3) rating the reasons for each patient's bizarre responses.

For the first stage, each patient was given the Proverbs Test (17) and the Social Comprehension Test (16) during an acute stage of his or her disorder. The patient's responses were later scored for idiosyncratic, bizarre verbalizations on a standardized scoring system reported previously (18, 19). Three accurate or near accurate responses and five idiosyncratic or unusual responses of each patient were selected for subsequent inquiry to him.

In the next phase, which occurred the following week, a senior psychiatrist conducted a standardized taped interview to explore the patient's reasons for and thinking involved in giving each of the eight responses chosen for analysis. The psychiatrist prefaced the interview by saying he was interested in greater detail about the patient's responses and in learning what the patient had in mind when he gave them and what types of things had led him to give these responses. This was followed by a series of structured questions for each response, such as "Do you remember what you were thinking of when you gave that answer?" "What led you to make that response?"

Third, the taped interviews were rated along standardized dimensions hypothesized to be underlying reasons for disordered thinking in schizophrenia. Thus, patients were rated according to whether their own specific bizarre responses were influenced by 1) faulty logic, 2) an intermingling of material based on their past or present experiences, 3) concrete thinking, 4) emotional overreactions to the questions, 5) delusional or paranoid ideation, etc.

Intermingling was considered present when there was overt evidence in the original response or the taped interview of the patient's blending material from his own experience into his response, or when the patient's answer was obviously guided or influenced by these experiences from the very beginning of the response.

The interviews and ratings also explored the possible presence of a number of factors that might be related to or influence intermingling or bizarre language, and these are reported in the current paper. Satisfactory interrater reliability was achieved for the ratings.

RESULTS AND DISCUSSION

Is Intermingling an Influence on Bizarre Language?

As noted above, intermingling is considered present when the patient blends into his response, or when the response is guided by, material from his past or current experiences that does not "fit" neatly and makes the response seem at least somewhat strange. Half (51%) of the schizophrenics showed strong evidence of overt intermingling and 27% showed milder evidence of intermingling. Overall, in a larger sample than we used in our previous research, the importance of intermingling in schizophrenic bizarre language was suggested. Strong evidence of intermingling was shown in 38% of the nonschizophrenics.

The data indicate that more of the schizophrenics than nonschizophrenics engaged in intermingling, but this difference was not statistically significant. Thus, the data suggest that the processes involved in intermingling are not unique to schizophrenia. They tend to be slightly more common in schizophrenics but also occur in many nonschizophrenics.

In previous research we found evidence that schizophrenics are not the only patients with thought pathology. Nonschizophrenics also show evidence of disordered language, although in nonmanic patients this is less frequent, less flagrant, and less severe (6, 11).

The data raise the possibility that intermingling material from one's own life is one of several general characteristics that might underlie many bizarre verbalizations, regardless of diagnosis. The issue here is whether whatever mechanisms are involved in idiosyncratic language in schizophrenia are also prominent factors for nonschizophrenics on those less frequent occasions when they do give idiosyncratic verbalizations.

Is Schizophrenic Intermingling Due to Preoccupation with One Central Problem Area or Emotional Complex?

The results in this area have some bearing on older theories that schizophrenic patients have one central "complex" or problem area and that preoccupation with this area dominates their lives, leading to emotional disturbance and possibly to interference and disruption of behavior.

The data indicate a clear trend for each schizophrenic's intermingling to be centered around a variety of topics or areas from his experience (three or more areas), rather than only one central problem area. This tendency occurred for 18 of the 25 schizophrenics who

showed evidence of intermingling (72%). Only 1 of 25 (4%) showed intermingling in only one area. Results were similar for nonschizophrenics.

Our results in this area were geared to answer a key question: is there one dominating problem to which the patient responds when he becomes psychotic, or does a vulnerable patient tend to respond strangely to almost any topic of concern that leads to idiosyncratic language? Our data suggest that one important factor in the schizophrenic's strange and idiosyncratic appearance is a tendency to intermingle overtly material from a variety of conflicts and concerns.

Possible Influences on Intermingling or Disordered Language

Overelaborate verbalizations and thinking. The results in table 1 reflect patients' tendency to give extensive and overelaborate verbalizations, which suggests elaborate sets of thoughts and possible overinvolved thinking about a topic. Dramatic examples of this feature in select patients have been noted by many clinicians.

Overelaborate thinking was not common in the schizophrenics (only 30% showed any signs thereof). It did appear, dramatically, in select patients. Detailed analysis indicated a tendency for overinvolved thinking to be associated with a smaller subgroup of paranoid schizophrenics.

These results indicate that overelaborate ruminative thinking is not characteristic of most early schizophrenics and is not an important mechanism in their intermingling or their bizarre behavior. However, a subgroup of early paranoid schizophrenics showed overelaborate verbalizations and thinking. Further exploration to determine whether overelaboration plays an important role for some paranoid schizophrenics might be profitable.

Strong emotional responsivity. Table 1 reports the results on strong emotional responsivity to the relatively neutral proverbs as an influence on patients' bizarre verbalizations. These data do not bear on whether or not the stimuli or emotional environment were emotionally laden. Strong emotional responsivity as an influence on disordered verbalizations tended to occur slightly more frequently among nonschizophrenics than schizophrenics (58% versus 30%), but this difference was not significant. Thus, strong emotional responsivity showed some influence on the nonschizophrenic patients' idiosyncratic language—although it usually was not the only or major influence—and relatively little influence on the schizophrenics.

Paranoid and delusional material. Delusions were very frequent among these young schizophrenics and may be an important influence on their overall behavior, but delusions usually were not the major determinant of their bizarre language (see table 1). In select, very dramatic cases, delusions were the major influence on the patients' bizarre verbalizations. These cases, however, were rare. Surprisingly, the influence of paranoid material on bizarre responses was not greater for paranoid schizophrenics than for nonparanoid schizophrenics. It must be remembered, however, that many nonparanoid schizophrenics also show some degree of paranoid ideation, although it is less frequent and less sustained.

TABLE 1
Patients with Disordered Language Influenced by Overelaborate Verbalizations, Strong Emotional Responsivity, and Delusional or Paranoid Ideation

Influences on Disordered Thinking	Schizophrenics (N=37)		Nonschizophrenics (N=16)	
	N	%	N	%
Overelaborate verbalizations or overinvolved thinking				
Very clear evidence	5	14	3	19
Minor evidence	6	16	0	0
No evidence	26	70	13	81
Strong emotional responsivity				
Very clear evidence	4	15	4	33
Minor evidence	4	15	3	25
No evidence	18	70	5	42
Unavailable for rating	11	—	4	—
Delusional ideation				
Very clear evidence	5	19	0	0
Minor evidence	3	11	0	0
No evidence	19	70	12	100
Unavailable for rating	10	—	4	—
Paranoid ideation				
Very clear evidence	7	19	2	13
Minor evidence	10	27	1	6
No evidence	20	54	13	81

Overall, almost all of the schizophrenics had delusional or paranoid ideas, and some paranoid material entered into the bizarre verbalizations of 46% of the sample. During the early stage, however, delusional or paranoid ideas were not the major factors in shaping the schizophrenics' bizarre idiosyncratic responses.

COMMENT

Intermingling and Disordered Language

The current investigation supports our previous research indicating that one immediate mechanism responsible for many young schizophrenics' bizarre verbalizations is a tendency to intermingle into their language or allow it to be guided by material from their personal experiences. At times the intermingling can often be found in nonschizophrenics who give strange verbalizations.

The results are not at variance with clinical observations and research demonstrating that schizophrenics' language contains features which can be viewed as bizarre, idiosyncratic, autistic, or disordered (1, 3, 7, 10, 19). However, the present data and our previous results (8) suggest that these strange verbalizations are based on rationales which make some sense in terms of patients' own experiences when looked at from their points of view.

Since nonschizophrenics typically show less

thought pathology, we would propose that personal experiences dominate their verbalizations less, and when they do appear they blend into or guide their responses in a more socially acceptable and better disguised fashion. For the nonschizophrenic, the compromise between adhering to the topic and expressing part of one's personal concerns is an imperfect one but is more closely attuned to the listener's probable reaction and the consensually correct subject of discussion.

Aspects of Intermingling and Its Determinants

Other information emerged about intermingling and the type of material involved. Delusional and paranoid ideation usually were not the major determinants of the schizophrenics' bizarre language. The material that intermingled into the patients' verbalizations and made them appear bizarre was not typically a result of overelaborate thinking or of overinvolvement with one central conflict.

The intermingled material usually came from several different personal experiences or conflicts for each schizophrenic. These concerns were not necessarily more serious than those experienced by nonschizophrenics. The major factor was the schizophrenic's tendency to blend the concerns into his or her verbalizations at times when their "fit" with the topics was poor. The intermingling of this material often shifted the schizophrenics' comments away from the consensual response, without any explanation to the listeners.

Perspective-Monitoring Ability and Disordered Language

What is the underlying factor that leads schizophrenics to intermingle material from their personal lives into their verbalizations? We would propose that one important influence involves executive processes, namely, the schizophrenic's difficulty in maintaining perspective about whether his own behavior is socially appropriate and monitoring his own language (perspective-monitoring ability). The normal person is typically able to maintain perspective (about what is socially appropriate) and to monitor his language such that his preoccupations do not enter into his verbalizations in a gross, bizarre manner. At times, however, these concerns do appear in the normal person's language in minor, partially disguised ways.

As formulated here, a prominent factor in schizophrenia is a disorder of that aspect of executive functioning involved in maintaining perspective about the social appropriateness of one's own behavior and monitoring it to conform to the social demands of the situation. At the time of his strange, idiosyncratic behavior the schizophrenic may have temporarily lost the ability 1) to maintain perspective about and recognize what is idiosyncratic to him versus what is appropriate in a social setting, and 2) to monitor his routine, minute-by-minute behavior such that his everyday concerns and wishes do not intermingle inappropriately into it. According to this hypothesis one would expect the schizophrenic to have better perspective about the social appropriateness of other patients' language than about his own, and we are currently undertaking research to assess this assumption. Nonschizophrenic patients and normals may also have some, but less, trouble in monitoring their verbalizations, leading to small amounts of cognitive slippage, especially during periods of stress or upset.

Acupuncture Treatment of Schizophrenia: Report on Three Cases

BY JONATHAN KANE, M.D., AND WILLIAM J. DI SCIPIO, PH.D.

The authors conducted a 9-week blind controlled study of the effects of acupuncture on schizophrenic illness in three patients on an inpatient ward of a psychiatric hospital. The patients were used as their own controls. The authors compared the effects of acupuncture, pseudo-acupuncture (random needling), and no-treatment control periods. Two patients who had had florid schizophrenic symptoms responded positively to true acupuncture treatments and negatively to pseudo-acupuncture. The third patient, whose symptoms were primarily affective-depressive, showed no significant response to treatment. The authors explore the mechanisms thought to be involved in the etiology of schizophrenia, focusing on the cortical arousal hypothesis.

ACUPUNCTURE, along with Western chemotherapy and Chinese herbal medicine, is being used in mental hospitals in the People's Republic of China to treat schizophrenia and other mental disorders. The Chinese have published material listing acupuncture points used in the treatment of the mental disorders that they diagnose as we do. According to an NIH publication (1), a 1971 Chinese text lists diagnostic categories and criteria for mental disorders along with recommendations for treatment. For example, schizophrenia is diagnosed by "broken thoughts" (loosening of associations), "disharmonious feelings" (withdrawal and inappropriate affect), and "delusions and hallucinations." The book lists body and ear acupuncture loci for the treatment of schizophrenia along with instructions for needling and for giving phenothiazines.

An uncontrolled study conducted at the Hopei Psychiatric Institute in 1957 (2) found that of 30 schizophrenic patients given an average of 8.2 acupuncture treatments, 73.4% "responded best, while the poorer therapeutic responses were obtained in chronic patients." Bresler and associates (3), citing a report of a Norwegian medical group visiting the People's Republic of China, stated that a 74% improvement rate was achieved in schizophrenic patients treated by acupuncture and neuroleptics.

According to a personal communication from Jean-Claude Darras, M.D., former Director of Training, Institut du Centre d'Acupuncture de France, schizophrenia is rarely treated by needling in France, where acupuncture is more widely practiced than it is in other Western countries. However, Soulie de Morant (4) and Van Nghi (5) listed acupuncture points for neurotic as well as psychotic syndromes.

The purpose of the present paper is to present a clinically controlled study of the treatment of three schizophrenic patients by acupuncture in the absence of neuroleptic medication. The design of this study is intended to provide objective assessment of treatment versus placebo effects of acupuncture on a range of psychiatric symptoms occurring during a course of treatment, using each patient as his or her own control.

METHOD

Patient Selection

Consecutive admissions to a 35-bed coed general psychiatric ward of a large urban state psychiatric hospital were screened for possible inclusion in the study. The patients selected had to have one or more of the following psychiatric symptoms on interview: loosening of associations, flat or inappropriate affect, or any two Schneiderian first-rank symptoms. Informed consent was obtained.

All patients were told that although success with this form of treatment has been reported in Eastern countries, no systematic studies were available in the United States. If the patient requested termination of the acupuncture procedure at any time, the treatment regimen was changed to more traditional Western approaches.

Design

Treatments were administered by the ward psychiatrist (J.K.) each weekday in individual 45-minute sessions. The points used are described in a Chinese publication (6). Two sets of points were used in alternation on successive days. The first set was the large intestine

Dr. Kane is Psychiatrist, South Beach Psychiatric Center, 777 Seaview Ave., Staten Island, N.Y. 10305. At the time this paper was written he was Psychiatrist, Bronx Psychiatric Center, and Instructor in Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. Dr. Di Scipio is Director of Psychology, Bronx Children's Psychiatric Center, and Assistant Professor of Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y.

The authors would like to thank the staff of Ward 5 of the Bronx Psychiatric Center and Conrad Mehler, M.D., for their help.

0002-953X/79/03/0297/06/$00.55 © 1979 American Psychiatric Association

4, the liver 3, and the governing vessel 26. The second set was the *T'ai-Yang*, the pericardium 6, and the spleen 6. After one week of needling, the following points were added to both sets: the governing vessels 13, 14, and 15 and the small intestine 19. Patients nearly always reported feeling something like an electric current flowing when the needles were placed in the true meridian points. This phenomenon is known as *te Ch'i* and is considered good evidence that the needle is in the correct position.

A pseudo-acupuncture procedure consisted of selecting placebo locations close to the true points but not corresponding to any known meridian, extraordinary, or "new" points. No feelings of *te Ch'i* were described by patients when these placebo locations were used. The equivalent type and number of needles, twirling time, and overall session times were maintained to correspond to the true acupuncture periods. Routine blood tests, urine analysis, and EEGs were within normal limits for all three patients. The no-treatment control periods consisted of scheduled equivalent-time individual sessions with the psychiatrist to maintain a concerned doctor-patient relationship without physical contact.

We used a within-subjects design with each patient acting as his or her own control. Each patient included in the study was rated by means of the Psychotic Reaction Profile (PRP) (7) for a baseline measurement after spending several days on the ward. Weekly PRP measurements were taken for a total of nine weeks. The baseline period lasted five days, and all other treatment and placebo periods were of two weeks' duration. Each patient received the following sequence of treatments staggered among patients: no treatment (baseline), acupuncture, no treatment (control 1), pseudo-acupuncture, and no treatment (control 2). The order of treatment was not randomized because the small sample size did not lend itself to statistical testing of an order effect.

Ward staff were aware of the use of acupuncture in the study but were blind to the design sequence. In addition, neither patients nor staff were aware of the difference between true acupuncture and pseudo-acupuncture procedures.

Measurement

The PRP is a rating scale designed for ward staff administration. It consists of 85 true-false items summarized by four scales: withdrawal, thinking disorganization, paranoid belligerence, and agitated depression. The PRP was rated independently by three paraprofessionals at least weekly. Two of these paraprofessionals were assigned to the day shift and one to the evening shift. Interrater reliability coefficients for the two day staff members were higher than coefficients between day and evening staff. The lower correlations between day and night staff are attributable in part to the different observation periods. To gain an accurate estimate of overall patient behavior, all three PRP raters' scores were averaged for each week for the purpose of the analysis (8). Averaging was necessary because on some occasions only one or two of the raters were present, according to their weekly staffing schedules. A two-way analysis of variance of patient differences, treatment differences, and interaction of these two independent variables was applied to each of the four PRP scales. The minimal acceptable level of statistical significance was .05.

CASE REPORTS

Case 1. A was a 16-year-old high school student who had seen the film *The Exorcist* about two months before admission. After seeing the movie he became more "nervous" than usual. For about a week before admission he refused to go to school. Several days before admission he began to develop florid delusions that the Devil was going to get him. He began talking to himself and felt that he was a policeman. On the day before admission he hallucinated that a giant fly was coming to kill him. He attacked his brother with a knife, causing some superficial throat wounds.

On admission A was fully oriented and showed no loosening of associations. He was withdrawn and guarded in his responses during the admission interview. His affect was inappropriately flat, particularly when he related the series of incidents described above. His history revealed that he had always been a loner and had no girlfriends. At school he could not pay attention to his work and usually engaged in grandiose fantasies about space travel. One year before this admission he had been referred by the school to a psychiatrist, who placed him on thioridazine for an unspecified period of time. The patient reported that his problem related to the fact that he was "bored" with school.

A was diagnosed as having schizo-affective schizophrenia (depressed). His baseline PRP values were as follows: withdrawal, 72nd percentile; thinking disorganization, 68th percentile; paranoid belligerence, 45th percentile; and agitated depression, 76th percentile.

Case 2. B was a 25-year-old single man who was admitted after becoming highly agitated the night before, when he walked home carrying a large cross and saw visions of God and the Devil. He disrobed at home and tried to put his mother into the oven because he thought she was Hitler and the Devil. On admission B was highly agitated and was experiencing auditory and visual hallucinations with religious and rebirth themes. His affect was flat, and he spoke in a monotone. He was fully oriented but had severe loosening of associations. Two months before admission this patient had also seen *The Exorcist*. At that time he started to have insomnia and began to keep a light on when he went to bed. On the day before admission the patient had gone to the cemetery for the unveiling of his father's tombstone.

This was B's first admission. He was diagnosed as having acute schizophrenia. His baseline PRP values were as follows: withdrawal, 32nd percentile; thinking disorganization, 95th percentile; paranoid belligerence, 82nd percentile; and agitated depression, 35th percentile.

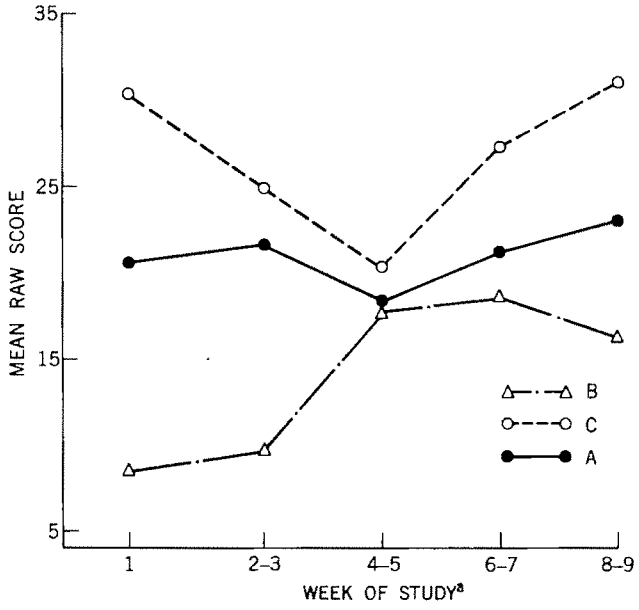
Case 3. C was a 45-year-old single woman who was admitted at her father's request after she pulled down his pants to check his prostate "to see if he's a real man." She said that she wanted to come to the hospital because it was "cold at

home." On admission C was grossly psychotic with delusions of a man who would marry her and with whom she would have a baby. (This delusion apparently involved a man who had called her once many years ago.) C showed loosening of associations, was extremely withdrawn and guarded, and responded to hallucinated voices. Her affect was inappropriate with frequent out-of-context chuckling. Her eyes looked wild and glazed, she exhibited bizarre hand mannerisms, and she walked in a stiff, stork-like fashion.

C had been hospitalized many times during the past three decades, living at home with her parents in the intervening periods. Her last psychiatric hospitalization had been four years before this one. She was diagnosed as having chronic paranoid schizophrenia. Her baseline PRP values were as follows: withdrawal, 93rd percentile; thinking disorganization, 80th percentile; paranoid belligerence, 49th percentile; and agitated depression, 93rd percentile.

RESULTS

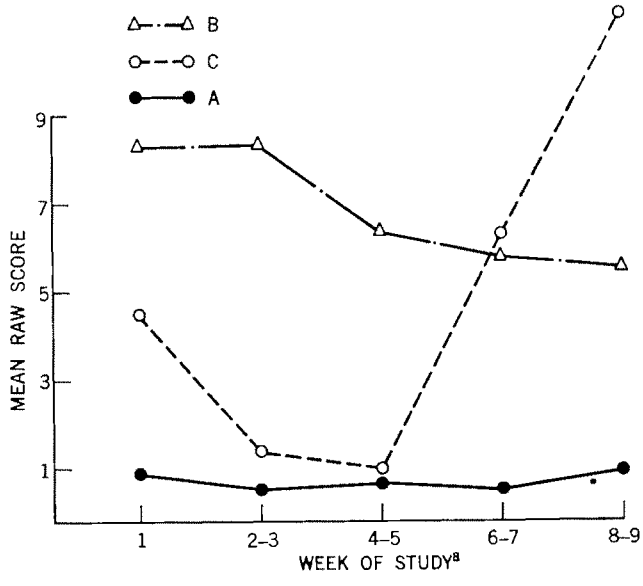
Case 1



Of the three patients, A seemed to respond the least dramatically to acupuncture treatment. His hallucinations cleared before any of the needling was performed and did not return during the course of the study. During the period of true acupuncture treatments he appeared to be more cooperative, more animated, and less withdrawn. On several occasions immediately following true acupuncture he indicated that he felt calmer and said with a smile that he was no longer bored. During the periods without acupuncture he did not seem to change at all with regard to withdrawal or other symptoms. No change was noted during the pseudo-acupuncture period with the exception that on several occasions he reported feeling more tense.

A's lack of response to treatment is shown in the results of three PRP scales (see figures 1, 2, and 3). Although the agitated depression scale appears to demonstrate a consistent decline in pathology (see figure 4), caution must be used in interpreting this scale because it is the least reliable of the four scales (7). Furthermore, no significant treatment effects emerged for this scale.

Case 2



During the several days before the acupuncture treatment B was often placed in the isolation room because of disruptive behavior that was not controllable by staff intervention. As soon as true acupuncture treatments began, the amount of time the patient spent in the isolation room was markedly reduced. During the control 1 period and especially in the second week of this period the patient began leaving the ward without permission and was again placed in the isolation room, although not as often as he had been during the first weeks of admission. During the needling periods, when the patient was asked in a nondirective way how he felt at the end of a session his typical response following a true acupuncture treatment was that he felt calm or relaxed. His responses following pseudo-acupuncture sessions were typically that he felt the same

or worse. Toward the end of the second week of pseudo-acupuncture he refused to continue needling treatment. He was then given chlorpromazine, starting at 150 mg t.i.d. and increasing to over 2000 mg within a month. During this month and the following two months there was no noticeable change in the degree of agitation, thought disorder, or hallucinations. It seemed that the behavioral changes occurring during

the acupuncture period were more pronounced than those during the pseudo-acupuncture and chlorpromazine periods.

The changes in the withdrawal scale for B showed a particularly labile picture (see figure 1). Following true acupuncture his scores increased considerably throughout the control 1 and pseudo-acupuncture periods. They then began to drop off during the control 2 period. The main treatment effect (a measure of pooled patient results among experimental periods) was significant. The interaction effect (patients by treatments) approached significance for this scale ($p<.10$). A planned comparisons test revealed that acupuncture versus pseudo-acupuncture, acupuncture versus control 1, and control 1 versus control 2 were each significantly different. Although these results represent pooled patient effects, B's main score changes were particularly large in magnitude, showing an 86% increase from acupuncture to control 1 periods. There was a consistent decline of B's scores on the paranoid belligerence scale following acupuncture (a decrease of 47% between true acupuncture and control 2 periods). This is reflected in the significant interaction for this scale (see figure 2). The thinking disorganization scale also showed a significant main treatment effect, indicating that there was a significant difference in this variable among experimental periods. A planned comparisons test showed that this effect occurred between control 1 and control 2 periods. B contributed most to this difference, showing a 30% decline in his mean thinking disorganization scores over this interval (see figure 3). The significant interaction effect (patients by treatments) for this scale supports the above analysis of B's contribution to the treatment effect.

Case 3

C was withdrawn, suspicious, paranoid, delusional, and actively hallucinating on the ward before her acupuncture treatments. During the course of the study, especially during the second week of true acupuncture, she became less guarded, began to talk more, and became relaxed enough to smile appropriately on occasion. She interacted much more with the staff and patients. This change lasted for about a week and a half after the first course of acupuncture. She then dramatically deteriorated, again becoming withdrawn and apparently hallucinating. She improved somewhat during pseudo-acupuncture. At the completion of the study she was given the same dosages of chlorpromazine that were given B. C improved within a month, returning to the level she had achieved by the end of the true acupuncture period.

C's deterioration during the middle of the study was corroborated by the PRP finding that a dramatic increase in paranoid belligerence occurred at pseudo-acupuncture and control 2 periods. A significant patient by treatment interaction was found (see figure 2). C also showed a similar deterioration as measured by the withdrawal scale (see figure 1). Although agitated depression scores were similar to the withdrawal scores no statistically significant difference emerged for the agitated depression scale (see figure 4).

DISCUSSION

Trends in improvement after true acupuncture treatments and subsequent deterioration in the direction of baseline values can be seen in figures 1 and 2. In the case of the withdrawal scale the trend achieves statistical significance. The withdrawal scale shows that B was rated by the ward staff as minimally withdrawn on admission because of his demanding excessive interaction. During the true acupuncture and control 1 periods, the staff's ratings indicated that they viewed the patient as having improved (withdrawal for this patient was an improvement). However, their ratings immedi

ately before and during the pseudo-acupuncture periods indicate that they viewed the patient as reverting to his original behavior at admission.

C, who was rated as very withdrawn on admission, was rated as having improved with true acupuncture treatments; her maximum improvement was reached during control 1 and worsened just before and during pseudo-acupuncture.

The fact that both B and C continued to show improvement in their staff ratings during control 1 is consistent with effects often observed in acupuncture treatment of physical conditions. The maximum effect of a session often does not become manifest until a few days later. The fact that both of these patients began to worsen before and during pseudo-acupuncture argues against a placebo or hypnotic effect.

Although research findings with acute schizophrenic patients are not conclusive, there is general agreement that chronic schizophrenic patients display heightened sympathetic tonus and a heightened baseline level of physiological arousal (9). In addition, Goldstein and associates (10) reported a high level of cortical activation in chronic schizophrenic patients.

There is a group of Chinese studies showing that acupuncture points such as those used in this study can influence cortical activation and the responsiveness of the reticular activating system to peripheral stimuli. Researchers at the Shanghai College of Traditional Medicine (11) have shown that electrical responses of the midbrain reticular formulation to peripheral pain stimuli are entirely or partially inhibited by stimulation of the acupuncture point stomach 36. Similarly, a group at the Peking Medical College (12) reported that needling of acupuncture points large intestine 4 and pericardium 6 inhibited cortical evoked potentials produced by stimulating the thyroid region. On the other hand, acupuncture has been successfully used to raise the level of cortical arousal in patients in coma, with awakening occurring in some cases (13).

Other studies have shown that the same points can act in opposite directions depending on the baseline state. Of particular interest is a 1959 report from the People's Republic of China on the effect of acupuncture on the EEGs of epileptic patients (14). Using the same combination of points (including some used in the present study), one group of epileptic patients showed cortical synchronization (decrease in cortical arousal) while another group showed desynchronization (increase in cortical arousal). The authors stated, "The occurrence of the phenomenon of synchronization or desynchronization appears to depend on the level of the cortical excitation state at the time of stimulation." According to Ying-k'un and associates (14), similar results have been reported by Tang for normal subjects.

Further studies have shown that acupuncture can act to correct either a hyperfunctioning or hypofunctioning of the autonomic nervous system. Researchers at the Peking College of Medicine (15) reported that stomach 36 can correct either diarrhea or constipation. Another study from the People's Republic of China (16) reported that stimulation of the upper lip had no effect on normotensive animals but had a powerful effect in reversing hypotension and shock produced by experimental bleeding. This gives credence to the impression of clinicians that a treatment usually has an effect only if there is pathological imbalance.

The present study shows that acupuncture, when correctly performed, exerts therapeutic action, possibly by decreasing the level of sensory input to the reticular activating system and thereby lowering excessive cortical activation and concomitant elevated sympathetic tonus. Whether or not this mechanism applies to other diseases treated with acupuncture remains unanswered.

APPENDIX 1
The Traditional Chinese Hypothesis

The traditional concepts of mental and physical disease in Chinese medicine arise out of ancient Chinese natural philosophy and science, particularly that of Taoism. According to the theory set forth in the *I Ching* and *Nei Ching* several

thousands of years ago, the universe has arisen out of a primordial energy, *Ch'i*, which evolved by a dialectic process into two polar forces, the yin and the yang. All natural processes of change, at any level of organization, can be understood as a simultaneous dynamic interplay of the yin and the yang elements, which are simultaneously complementary and antagonistic.

Yang corresponds to movement, expansion, sun, spring, summer, heat, and day. In the human body yang corresponds to the upper part of the body, the back, and the "hollow" organs (stomach, gall bladder, urinary bladder, large and small intestines). Yin corresponds to quiescence, condensation, contraction, moon, autumn, winter, cold, and night. In humans it corresponds to the lower part of the body, the abdomen, and the "solid" organs (liver, heart, blood, spleen, lungs, and kidneys).

Traditional Chinese theory states that *Ch'i* flows in cyclic patterns throughout the body by means of a network of superficial meridians connected to the internal hollow and solid organs. Disease arises when the normal homeostatic flow is interrupted, leading to excesses, deficiencies, and stases of energy. Both somatic and psychological consequences can result from such energy dysfunction, since a yin-yang imbalance affects the organism holistically.

The major factors producing imbalance are meteorological influences (cold, humidity, etc.), excessive emotions, and dietetic irregularities. In traditional acupuncture therapy, one acts on the bodily dysfunctions by means of needling the necessary acupuncture points to restore the proper energy balance. In the case of schizophrenia, the cause is a deficiency of yin and an excess of yang. The weakened yin cannot harmonize with the yang, which partially separates from it. The yang, being mobile, agitated, and light, rises to the upper part of the body, including the head, giving rise to psychotic symptoms. To treat this condition one augments the yin and disperses the yang to restore balance and reintegration.

Although the above may seem abstruse or metaphorical, it represents the ancient theoretical explanation for both the etiology of schizophrenia and the mechanism by which acupuncture treatments produce an improvement in symptoms. Interestingly, the modern Western theories referred to above to explain the action of acupuncture share with the Chinese philosophy a dialectic process that views schizophrenia as the result of an imbalance between opposing but normally complementary factors.

Special Issue of *AJP* to Feature Depression and Alcoholism

A special issue of the *American Journal of Psychiatry* will be published in mid-April 1979. This issue, which will be distributed to all subscribers and is in addition to the regular April issue, will consist of a collection of articles on the subjects of alcoholism, depression, or both. Articles will deal with such topics as the treatment of depression with imipramine and ECT; bipolar illness: factors in drinking behavior; physical activity and plasma cyclic AMP in manic-depressive patients; childhood depression; life events at the onset of bipolar affective illness; psychiatric problems in women at alcoholic detoxification; lithium maintenance; efficacy of drugs and psychotherapy in the treatment of acute depressive episodes; and life events, coping, stress, and depressive symptomatology.

Authors include David Avery, M.D., Jesse O. Cavenar, Jr., M.D., David L. Dunner, M.D., Ronald R. Fieve, M.D., Eric W. Fine, M.D., Evelyn L. Goldberg, Sc.D., John Hamm, M.D., Shirley Hill, Ph.D., Eleftherios Lykouras, M.D., Anthony Marsella, Ph.D., Roy Mathew, M.D., Jerome Motto, M.D., Irving Philips, M.D., Timothy Rivinus, M.D., Fred Steinberg, Ph.D., Marc Schuckit, M.D., Robert Belmaker, M.D., Martin Keeler, M.D., Paul Garfinkel, M.D., John Helzer, M.D., James Kocsis, M.D., Myrna Weissman, Ph.D., Alberto DiMascio, Ph.D., Gerald Klerman, M.D., Larry Ereshefsky, Pharm.D., Michael R. O'Leary, Ph.D., Steven J. Wolin, M.D., George J. Warheit, Ph.D., and Walter A. Brown, M.D.

Extra copies of the special issue will be available from the APA Circulation Department at a cost of $2.25 for domestic orders and $2.90 for foreign orders. Payment must be included with order.

Standards Affecting Mental Health Care: A Review and Commentary

BY SCOTT H. NELSON, M.D., M.P.H.

The author describes the increasing focus on regulation and the standards applied to the field of mental health. He discusses four distinct but overlapping types of standards: 1) clinical, 2) practitioner, 3) program and facility, and 4) payment. He emphasizes the increasing influence of legislation and judicial decisions and points out several trends in standard setting affecting mental health care. Psychiatrists and other mental health practitioners are called on to take a larger role in shaping these standards to ensure that the quality of patient care is not compromised.

THE AGE OF REGULATION is upon the mental health field. No longer can we mental health professionals sit in our private offices, universities, or administrative posts and carry on our activities in the way we were trained to do them. Now institutions and programs must be licensed or accredited, providers must be certified or licensed to practice, and the care we provide is coming under increasing scrutiny by our peers, the public, and third-party payers.

In the past few years an additional influence has joined the regulatory process: the legislative process and the decisions of courts regarding various aspects of mental health care. Some of these judicial decisions have been far-reaching indeed, relating to such fundamental issues as the right to treatment, the right to least restrictive care, and even to such forms of psychiatric treatment as ECT.

The heart of the regulatory process is the application of criteria or standards. According to Webster, a standard is a measure established by authority, custom, or general consent as a model or example—a measure set up by authority as a rule for determining value, extent, or quality. Since the term "standard" denotes a measure, it should be remembered that standards are set by some individual or group for some other individual or group.

Received March 6, 1978; revised April 10, 1978; accepted July 18, 1978.

Dr. Nelson is Director, Behavioral Health Services Division, New Mexico Health and Environment Department, Santa Fe, N.Mex. Address reprint requests to him at 113 Washington Ave., Santa Fe, N.Mex. 87501.

KINDS OF STANDARDS

Because the idea and practice of regulation are new to mental health professionals and because the processes that are involved in regulatory procedures are sometimes complex, the types of standards relevant to the mental health field often appear confusing. In general, however, one can usefully characterize four specific, often mutually interactive kinds of standards that apply to the field of mental health. These include 1) clinical services standards, 2) practitioner standards, 3) programs or facilities standards, and 4) payment systems standards.

Clinical Standards

Clinical standards relate to specific aspects of clinical care. These include diagnosis of the emotional disorder, the appropriate modality for treating the condition, and how long and how often treatment should take place. One of the problems in the development and application of clinical standards is that the depth, reliability, and validity of knowledge about diagnosis, treatment, and outcome in the mental health field are not as objective or scientifically developed as they are in other branches of medicine. For this reason it is often difficult for mental health practitioners to agree on appropriate clinical standards.

Clinical standards in the mental health field are usually set by practitioners of a particular discipline. Examples are the peer review committees of local branches of the American Psychological Association and the American Psychiatric Association and the local clinical standards set by physicians under the Professional Standards Review Organization (PSRO) program. Critics of the peer review process have raised the concern that professional associations cannot and/or will not responsibly apply clinical standards to the care provided by members of their own profession. However, to date the medical professions have been provided the first opportunity to develop standards that will produce much needed improvement in the quality of clinical practice and avoid excessive and inappropriate care.

Over the past century certain treatment philosophies have become well established in the practices of mental health professionals and have been ingrained in the training programs that produce these professionals. However, the anticipated strong resistance of the mental health professions to the development and ac-

0002-953X/79/03/0303/05/$00.50 © 1979 American Psychiatric Association

ceptance of clinical standards has not occurred. Indeed, mental health professionals have been the leaders in developing and applying their standards to care. For example, the American Psychiatric Association was among the first professional associations in the field of medicine to prepare its criteria sets to be considered by local PSROs in the review of care (1). This lack of professional resistance may be related primarily to the fact that the field of mental health care has less ability to demonstrate its merits on a scientific basis to policy makers and third-party payers.

Related to the development of clinical standards is the evaluation of treatment outcome. This is another area fraught with difficulty and disagreement in the mental health field, particularly with regard to the standards and criteria that should be used. Although treatment methodology is improving and measurement techniques are becoming more sophisticated, the evaluation of treatment of mental disorder remains considerably inferior to similar evaluation of treatment in other medical practice. In part, this is the nature of the clinical disorders with which the mental health system deals, which are of such complexity that it is usually exceedingly difficult to demonstrate, for example, that the cause of improvement was treatment intervention rather than some other factor in a patient's life.

Practitioner Standards

Standards are applied by at least three different sources to practitioners in the mental health field: agencies of government (usually states), professional associations, and third-party payers. Each of these sources of practitioner standards applies overlapping but distinct standards that may differ according to the discipline of the practitioner.

For example, the process by which a state applies standards to mental health professionals is usually licensure. Licensing gives permission to engage in a profession or occupation after the state has determined that the individual has achieved minimal specified criteria. Nominally these criteria relate to the assurance that public health, safety, and welfare of the citizens of the state will be protected.

Certification is the process used by many professional and other disciplinary groups or associations to grant recognition to an individual who has met certain criteria specified by the association. The criteria may be the same as or different from the criteria used by a state in determining licensure. Certification may or may not be required for licensure and vice versa. For example, clinical psychologists in most states must be certified by their professional association before they can be licensed to practice in the state. On the other hand, physicians who have completed a year of internship and possess a license to practice medicine technically can call themselves psychiatrists and practice psychiatry, although few actually do. Psychiatrists are not required to obtain certification from the American Board of Psychiatry and Neurology in order to practice psychiatry. However, a fully trained psychiatrist must be licensed to practice medicine in a state before he or she can take the examinations for professional certification.

In general, standards used to determine whether or not an individual may be certified or licensed relate to the training, professional degrees, and experience of the individual. In addition, specific attempts at measuring competence of the practitioner may or may not be included. Considerable debate has occurred within the professions as to whether or not competence can be measured, particularly since agreement on standards of clinical care has yet to be reached in the mental health field.

Third-party payers also apply standards to practitioners in that they reimburse services provided by some mental health professionals but not others. For example, under some insurance plans and Medicare, only services provided by physicians can be reimbursed on a fee-for-service, independent-practice basis. Services provided by independently practicing clinical psychologists, social workers, nurses, and others are excluded. Increasingly, however, clinical psychologists have achieved a status similar to that of psychiatrists with insurance companies. In fact, this standard has been taken out of the control of the carriers in the case of the Federal Employees Health Benefits Program by legislation requiring all carriers to provide equal choice for beneficiaries between psychiatrists and psychologists. In addition, Medicaid now reimburses services provided by clinical psychologists in some states.

One of the important issues in the area of practitioner standards in the mental health field is whether or not the various mental health disciplines have done enough to assure that their practitioners are well enough informed and are practicing competently. Although the difficulties inherent in any process of determining competence are admittedly great, critics have pointed out legitimately that the various professions have taken on very little responsibility with regard to such issues as standards of practice or appropriate certification and licensure of members of the profession. In an earlier publication (2) I suggested that one's professional discipline may not be the most appropriate criterion on which competence, and thereby reimbursement, should be based. Rather, the ability to deliver competently a particular kind of service might be more objectively measured on the basis of training, experience, and proficiency tests developed independent of the discipline involved. The debate surrounding practitioner standards is likely to continue, particularly since such standards relate directly to access to reimbursement and the control of the professions over their own destinies.

Program and Facility Standards

Standards for programs or facilities are applied to a wide variety of settings, ranging from such service delivery programs and facilities as state, general, and private hospitals, health maintenance organization

(HMOs), community health and mental health centers, outpatient clinics, halfway houses, and other intermediate care settings to teaching and research programs. As with practitioner standards, program standards impinge on other areas of standards development and are often applied along with such other standards as client and practitioner eligibility.

A sharp distinction has often been made between program standards and standards for facilities. Program standards usually consist of criteria that apply to an organized systematic approach to service, teaching, or research that has specific process and outcome objectives. More often, facility standards have been applied to the mechanics of patient records, institutional sanitation and safety, and the condition of physical plants. Standards that apply to a facility may or may not include program standards. In recent years the review process has tended to scrutinize both physical aspects and the specific programmatic content that is provided by an institution or facility.

Program standards are most commonly applied by states (in the form of licensure), program or institutional associations (which develop standards to assure the quality of the programs or facilities they represent), third-party payers (in the form of requirements for licensure, certification, or accreditation), or teaching or research institutions (commonly in the form of criteria for the receipt of financial aid).

Perhaps the best known organization responsible for promulgating program and facility standards is the Joint Commission on Accreditation of Hospitals (JCAH). This organization was created in 1951 to develop minimum standards of care in hospitals. The JCAH carries on activities started by the American College of Surgeons in 1913 and has evolved to become the accreditation body for institutions and even nonhospital facilities that desire to participate in such third-party payment systems as private insurance, Medicare, and Medicaid. In essence, the JCAH provides a voluntary mechanism through which a facility can be certified as a provider under most of these financing programs.

In the past JCAH has been criticized because of its almost total emphasis on the physical and record-keeping aspects of facilities and its lack of attention to programs. However, recently it has started to develop program standards, including some that relate specifically to mental health, drug abuse, and alcoholism treatment systems. Obviously, changes have been slow and difficult to effect, primarily because of the different procedures and types of individuals needed to develop and promulgate program standards, compared with those needed to develop more technical and physical standards.

The linking of licensing, accreditation, and certification of institutions to reimbursement has been of increasing concern to mental health facilities, particularly those which are nontraditional or are not associated with a hospital setting. Facility and program standards are often not established for such settings; without them, programs are not eligible for most types of reimbursement under insurance and federal financing programs. Each of the three institutes of the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) has recognized this fact and has taken steps with JCAH to develop program standards for such new or existing treatment programs as community mental health centers and drug abuse and alcoholism treatment centers. The first surveys and JCAH accreditation of community mental health centers took place in 1976 (3).

Program and facility standards must be distinguished from program evaluation, in which the degree to which program objectives have been achieved is assessed. Meeting standards is often inherent in the process of accomplishing objectives. Conversely, having an adequate evaluation component is often a standard to which programs must adhere.

Carrying out any kind of meaningful program evaluation in the mental health field is a difficult challenge, complicated by lack of agreement on evaluation methodology, measures of program success, and even the specific objectives of the program. In the federal government, the multiple, often conflicting objectives for a program that are held by parties at varying levels of interest and authority make meaningful program evaluation a nearly impossible task.

In the process of establishing mental health program standards and program evaluation procedures, systems for collecting ever-increasing amounts of data have rapidly developed. Serious questions have been raised about the usefulness of these myriad reporting systems in the management and justification of program activities and about the burden they place on respondents in the field.

The standards and other regulations and requirements that are now applied to organized programs of mental health care are so extensive that in the near future it would not be surprising to see a return to less organized forms of mental health care, particularly solo private practice. Clearly, this raises the issue of the way in which standards and other regulatory procedures are applied; it also poses the question of how much is enough.

Payment Standards

The objectives of the standards developed and applied by such third-party payers as insurance companies, Medicare, and Medicaid are dramatically different from those applied to clinical services, practitioners, and service facilities. Payers' standards are spelled out in contracts or other formal mechanisms that describe the benefits and conditions between the payer and the subscriber or eligible client. In the case of most third-party financing programs related to health and mental health care, the goal of the payer is to meet the terms of the contract without incurring excessive costs. The primary mechanism to ensure this cost containment is by actuarial analysis and a claims review process that may or may not be carried out by a

health professional and does not necessarily conform to professional norms and criteria.

Because of the control by third-party payment systems of financial access for both the consumer and the professional, payment standards have been the subject of considerable discussion and controversy in recent years, particularly as the costs and use of both medical and mental health services have continued to rise. The power of payment standards is very great indeed. Third-party payers can determine what facility and program standards must be observed to obtain reimbursement as well as what practitioners will be eligible for reimbursement and under what circumstances. Of increasing concern is that professional standards of clinical care may or may not be used and accepted by third-party payers in reimbursement for service. Rates of payment may also become an issue, particularly in such tax-supported programs as Medicare and Medicaid. There have been substantial difficulties in obtaining practitioner cooperation in such programs because practitioners often feel that reimbursement rates are too low to make service delivery financially feasible.

Payment standards are particularly stringent in the mental health area. The Medicaid program, for example, will not reimburse for care delivered to individuals aged 21–64 in a psychiatric institution. Although some insurance carriers now allow the payment of independently practicing psychologists as well as psychiatrists, Medicare does not allow any practitioner other than a physician to collect reimbursement directly. Service provided by other mental health practitioners may be reimbursed in certain settings but only under the supervision of a physician; in addition, the reimbursement is made to the facility rather than to the individual provider.

One of the major issues relating to payment standards is the extent to which mental health, drug abuse, and alcoholism services are provided as options to subscribers of insurance programs or to clients eligible for other health financing programs. Although some insurance companies provide adequate coverage for mental disorders and substance abuse problems, most limit such coverage more than for physical disease; this is also true under the Medicare and Medicaid programs. In some states the concerns over these limitations have led to legislation requiring minimum mental health benefits in all insurance plans (4).

In part, discrimination against treatment for mental disorders by third-party payers is due to the fact that there continues to be bias and prejudice against individuals with emotional disorders. There is also concern about the overall cost and utilization rates for such conditions, especially if they are provided on an unlimited basis. Insurance companies and federal financing systems are concerned about lack of demonstrated efficacy of the treatment for certain types of mental disorder. The less favorable consideration of mental disorder by payment systems has been a subject of much controversy recently, particularly in the development of arguments for and against coverage of mental disorders in federally assisted HMOs and under national health insurance (NHI) proposals.

Payment standards that are responsive to the objectives of contract obligations and cost control have caused practitioners and concerned others to raise serious questions about the effect of such standards on the quality of care. In 1972, when a well-known insurance carrier was faced with a large potential cost overrun, types of claims that previously had been accepted were routinely denied for the remainder of that fiscal year.

Such a situation clearly delineates the difficulty in reconciling two very different sets of objectives and practices in the application of standards to clinical care—the objectives of cost containment versus quality care. On the one hand, practitioners point out that through the claims review process insurance companies are mandating not only the documentation but also the types of care that can be delivered and reimbursed. Insurance companies, on the other hand, claim that practitioners have failed to provide necessary criteria based on clinical standards and judgments by which claims review procedures can be carried out effectively. As the financial constraints grow tighter, this divergence in approach and viewpoint may widen and may require the intervention of an outside arbitrator for settlement.

THE LEGISLATIVE AND JUDICIAL SYSTEMS

The conflict between third-party payers and practitioners surrounding payment for care may very well be resolved in legislation or in the courts. The legislative and judicial systems have played ever greater roles in the past five years in the shaping of standards in each of the four areas discussed above. The reasons for this increased intervention are complex, but they probably have to do with the fact that health care of all kinds is perceived more and more as a proper concern of society as a whole rather than the sole domain of the physician and other practitioners. Medicine has become very big business indeed and, like other aspects of our free enterprise system, has increasingly evidenced the need for some form of regulation simply because of its size and cost.

There are many examples of the influence of legislation and judicial process on the mental health field. In the area of payment, one can point to the legislation mandating that psychologists be considered equal independent providers of service under the Federal Employees Health Benefits Program, along with several similar pending cases. Whether or not an institution that loses its JCAH accreditation becomes disqualified for Medicare and Medicaid reimbursement is an issue related to both payment and facility standards. Court decisions like *Wyatt v. Stickney* (5) have reaffirmed the rights of patients held against their will in institutions without treatment. In addition, several state legislatures have passed new and more stringent mental

health commitment codes in response to concern about patients' rights. Courts have also helped to set standards for staffing psychiatric facilities and have provided direction on how "treatment" should be defined.

In the clinical area, the number of malpractice claims continues to escalate yearly. The California state legislature has gone so far as to restrict the use of a major psychiatric treatment modality, ECT, by legislation and is considering a similar course for all psychotropic medications, an indication of the potential role of the legislative process in the regulation of day-to-day clinical practice.

FUTURE TRENDS

Current trends seem to indicate that the role of the practitioner in setting standards is decreasing, while the influence of payment and legal systems is increasing. The mental health field is particularly vulnerable in this situation because of the lack of well-defined and commonly accepted criteria for evaluation of clinical care, practitioner practice, and program activity.

The specific concerns of decision makers seem clear. It is widely held that a substantial proportion of practitioners are motivated by financial interest rather than by concern for patients. One insurance company official enjoys citing an example of the psychiatrist who filed a claim for individual psychotherapy for a four-month-old infant as well as separate claims for the child's parents. Insurance companies have also pointed out that it is difficult to determine from the processing of claims that treatment has been at all helpful to individuals, couples, and/or families in improving their functioning. The few instances of gross malpractice and unethical conduct that have occurred are well remembered by critics of the mental health field. In combination with the assumed lack of scientific basis for diagnosis, treatment, and outcome, these instances have tarnished the image of mental health practice as being particularly subject to incompetent and ineffective practice.

The increased influence of third-party payers and the legal system has resulted from the failure of mental health practitioners and other health professionals to regulate themselves. Although as practitioners we complain that the claims review process is arbitrarily managed and does not reflect sufficient professional input, we have made little effort to provide the necessary clinical criteria that would be useful in improving the process. In many instances we have been reluctant to participate directly in the review process. Instead of a collegial attempt to improve the standards of competence for practitioners by delineating which disciplines are capable of performing which kinds of services, there is continued jockeying of professions for standing within the reimbursement system. This contributes little toward winning the confidence of third-party payers, not to mention the needed support of an increasingly skeptical public.

Clearly, part of the difficulty in these areas has to do with the status and independence of the various practitioners to take on new and different roles as mental health professionals. Generally, our training has been in ways to gain clinical knowledge and skills and to apply them to service delivery. We have usually not been trained to deal with financial management, development of clinical standards and review mechanisms, or social policy issues. However, to the extent that mental health professionals continue to withdraw from these areas, third-party payers and the legislative and judicial systems will play an increasingly greater role in the control of clinical services, training, and research activities. The potential for arbitrary decisions in the area of clinical treatment becomes correspondingly greater.

It is encouraging that some attempts are being made by mental health practitioners to help the field become more accountable and to regulate itself. The number of conferences, books, and articles related to accountability of mental health practice has increased dramatically in the past five years. However, the commitment and involvement must be greater, and it must come from all of us if we want to shape the standards and regulatory processes that are applied to us. If we avoid this responsibility we risk significant compromise in the quality of care for our patients.

BRIEF COMMUNICATIONS

Paranoia and Platelet MAO in Normals and Nonschizophrenic Psychiatric Groups

BY RICHARD J. HAIER, PH.D., DENNIS L. MURPHY, M.D., AND MONTE S. BUCHSBAUM, M.D.

The authors compared the correlation between platelet monoamine oxidase (MAO) activity and the Paranoia (Pa) scale of the Minnesota Multiphasic Personality Inventory in several groups. The data suggest that there is a positive association between high MAO activity and high scores on the Pa scale but only in samples with psychopathology.

As researchers continue to identify tentative relationships between specific biological variables and psychopathology, one strategy for clarifying the meaning of such relationships is to study the same biological variables in nonpsychiatric samples. This strategy not only eliminates possible artifacts of hospitalization and drug treatment but also tests the specificity of the variable's relationship to psychopathology. A series of reports on platelet MAO activity differences between normal controls and three types of psychiatric patients—chronic schizophrenics (1), patients with bipolar affective disorders (2), and alcoholics (3)—has prompted several investigations of MAO correlates in nonpatient samples (4–6). These studies tend to support the existence of a relationship between MAO and psychopathology, but MAO appears to be related to a broad range of psychiatric problems. In view of this nonspecificity, the recent reports that paranoid schizophrenics (7, 8) and schizophrenics with auditory hallucinations (9) have lower platelet MAO activity than nonparanoid chronic schizophrenics are particularly interesting because they suggest a more specific involvement for MAO. Because the low-MAO/paranoia relationship has been questioned in other reports (10, 11), we decided to investigate the suggested relationship in nonpatient samples and in nonschizophrenic psychiatric patients by examining the correlation of platelet MAO activity with the Paranoia (Pa) scale of the Minnesota Multiphasic Personality Inventory (MMPI).

Received July 13, 1978; revised Sept. 18, 1978; accepted Oct. 17, 1978.

The authors are with the National Institute of Mental Health, where Dr. Haier is Staff Fellow, Laboratory of Psychology and Psychopathology; Dr. Murphy is Chief, Clinical Neuropharmacology Branch; and Dr. Buchsbaum is Chief, Section on Psychophysiology, Biological Psychiatry Branch. Address reprint requests to Dr. Haier at NIMH-LPP, Bldg. 31, Rm. 4C-35, Bethesda, Md. 20014.

METHOD

We reviewed all available data collected by NIMH researchers in which psychiatric patients and volunteer controls had completed both MAO and MMPI testing. A total of 352 subjects in five different projects fulfilled this criterion. In the Haier and associates project (12), 385 student volunteers were screened for psychopathology on the MMPI. An index group of the 36 subjects who scored more than 4 standard deviations above the standardized population mean on at least one of the clinical scales was identified. Subsequent psychiatric interviews revealed that 20 of these subjects met Research Diagnostic Criteria (13) for an affective disorder, but none met the criteria for schizophrenia. A control group of subjects who scored within 2 standard deviations of the population mean on all clinical scales also was selected. Major and associates (3) tested a group of Navy enlisted men who were in a special 6-week treatment program for alcoholism. Each subject completed both MAO and MMPI testing at admission and again at discharge. Buchsbaum (unpublished data) and Murphy and associates (14) tested randomly selected normal volunteer subjects. The fifth group consisted of patients with affective disorders who routinely completed the MMPI and MAO testing (during drug-free and diet-controlled periods) as part of their stay in an NIMH research ward.

Platelet MAO activity was assayed as reported by

[a]MAO was assayed with benzylamine and is reported in nmol/10^8 platelets/hour except for control sample data from Buchsbaum and from Murphy and associates, which are benzylamine equivalents derived by transforming the original tryptamine values with a special regression equation (15, p. 258).
[b]Data on MAO are from reference 3; Pa data were provided by the author.
[c]These means and standard deviations are raw score estimates transformed from standard scores.
[d]This correlation is probably attenuated because the sample was selected in a way that would exclude individuals with high scores on the Pa scale.

Murphy and associates (15). ^{14}C-Benzylamine was the substrate in all but the Buchsbaum and Murphy and associates normal volunteer samples, where ^{14}C-tryptamine was used.

The MMPI Pa scale is one of nine original clinical scales developed to assess psychopathology. Low scores on the Pa scale may indicate trustfulness and a lack of personal sensitivity to others and may be related to underachievement in college students. High scores tend to characterize people who are more concerned with themselves than with others and who are unable to deal with criticism. Very high scores indicate suspiciousness or paranoia (see references 16 and 17). The interpretation of MMPI scales depends on the relative elevation among all the scales, so reliance on a single scale typically is not useful. However, the Pa scale is a standard measure that is comparable among the different samples studied here and is a reasonable psychometric index of the paranoid construct.

RESULTS

Table 1 lists the MAO/Pa correlations for the samples defined by some kind of psychopathology and those for normal volunteer and control samples. Five of the six MAO/Pa correlations in the psychopathologic samples are positive and three are statistically significant (alcoholics at admission and discharge were counted only once). All five of the correlations in the control samples are negative and only one is significant. The sign difference of the MAO/Pa correlations between the two kinds of samples is statistically significant (Fisher exact test, $p<.02$).

Four of the significant correlations are in samples of 36 or more subjects. In these samples of satisfactory size, we calculated the correlations between MAO and each of the remaining MMPI clinical scales. In three of these samples, the MAO/Pa correlation was the only one to reach statistical significance. In the fourth sample (Murphy and associates, data for females), the Hysteria and Psychasthenia scales were correlated with platelet MAO (+.25 and +.33, respectively, $p<.05$).

DISCUSSION

The pattern of correlations in these samples suggests that platelet MAO is related to the Pa scale but only in samples defined by criteria of psychopathology. Moreover, the direction of the relationship, i.e., high MAO activity associated with high Pa scores, is opposite of what would be expected on the basis of paranoid schizophrenics having the lowest mean MAO levels of any psychiatric group. The subjects in the psychopathological samples reported here, however, are characterized by affective symptomatology rather than schizophrenia. If the subgroup of the Haier and associates MMPI index sample that meets RDC for affective disorders ($N=20$) is considered separately, the MAO/Pa correlation is .45 ($p<.05$).

The data from schizophrenic patients imply an inverse relationship between MAO and paranoia, but results for these affectively ill samples indicate a positive relationship. However, the MMPI Pa scale may not assess the same construct that is assessed by the clinical diagnosis of paranoia. Furthermore, paranoid individuals can successfully avoid responding to the obvious items on the Pa scale, which can lower their scores (see reference 16). This would attenuate the MAO/Pa correlation, but it would not account for the directional difference. Finally, with respect to the lack of a significant MAO/Pa correlation among normal control

groups, Winter and associates (18) also reported nonsignificant correlations between platelet MAO (tryptamine substrate) and the Pa scale in normal monozygotic and dyzygotic twins.

Differences in the functional relationships among variables within different psychiatric groups may provide clues for understanding the biological bases of certain psychopathological manifestations. How platelet MAO interacts with other neurochemical systems is not known, but a symptom manifestation like paranoia could result in part from a ratio between two or more opposing neurotransmitter systems. Thus, other biological differences between schizophrenics and affectively ill patients may determine the strength and direction of the MAO/Pa relationship. Some considerations of how multiple factors, including genetically based enzyme differences and various situational factors, may interact to yield different clinical phenomena have been discussed elsewhere (see references 3 and 19).

Phenylethylamine in Rhesus Monkeys: Interactions with α-Methyl-*p*-tyrosine and L-Dopa

BY JARED R. TINKLENBERG, M.D., J. CHRISTIAN GILLIN, M.D., GREER M. MURPHY, JR., RICHARD STAUB, AND RICHARD JED WYATT, M.D.

Rhesus monkeys, pretreated with α-methyl-p-tyrosine (AMPT) and subsequently injected with phenylethylamine (PEA), did not demonstrate the characteristic amphetamine-like PEA effects. However, when AMPT pretreatment was followed with L-dopa and then PEA injection, PEA effects were restored. These results are compatible with a dopamine theory of schizophrenia.

PHENYLETHYLAMINE (PEA), the endogenous parent chemical structure for the catecholamines, and its derivatives are of particular psychiatric interest.

1. PEA is structurally similar to amphetamine, lacking only the side chain methyl group. Recent studies in rodents and monkeys indicate that some, but not all, of the pharmacological and behavioral effects of PEA are similar to those of amphetamine (1–4). Amphetamine-induced behaviors are considered by many as a useful pharmacological model of paranoid schizophrenia (5–8).

2. There is at present no clear evidence that consistent tolerance develops to most behavioral effects of PEA (2, 9), although some pharmacological tolerance may develop (1, 10). Lack of consistent tolerance would be compatible with an endogenous substance that contributes to chronic psychiatric disorders such as schizophrenia.

3. Under certain conditions, neuroleptic drugs modify some of the PEA-induced behaviors in a pattern that approximates the clinical potency of the neuroleptics (11).

4. PEA is a specific substrate for monoamine oxidase (MAO) type B (12). Platelet MAO, most of which is type B, has been low in certain types of schizophrenia and hence in those individuals any effects of PEA might be exaggerated (13, 14).

In the present study, we further defined the effects of PEA in rhesus monkeys by making pharmacological manipulations with α-methyl-*p*-tyrosine (AMPT), L-3,4-dihydroxyphenylalanine (L-dopa), and phenobarbital.

METHOD

Experiment 1: AMPT-PEA Interaction

We studied six subadult *Macaca mulatta* that weighed 4–6 kg and were housed in individual cages arranged so that they could not see each other. Before receiving treatments, the animals were fasted for 24 hours.

Each of the six monkeys was pretreated with 125 mg/kg of AMPT or saline placebo three hours before challenge with 75 mg/kg of PEA or saline placebo. In a randomized block design, the six animals were studied during each of four treatment conditions: saline-saline; AMPT-saline; saline-PEA; AMPT-PEA. At least three days separated each treatment. AMPT and placebo pretreatments were administered by oral intubation in 10 ml of saline.

PEA and placebo challenge doses were given intramuscularly in 0.1 ml/kg of saline. The squeeze bar, a solid panel that could be moved so as to gently restrain the animal against the side of the cage, was used for the I.M. injections.

Two observers, both blind to the treatment conditions, simultaneously recorded two classes of behavior: checking and general activity. Checking was defined as any change in the visual field of the animal due to eye or head movements. The observers counted the number of individual eye movements (or head movements if the eyes were not visible) that occurred during a 15-second observation interval. The general activity score was based on 16 discrete, objectively defined categories of behavior scored as either present or absent during a separate 15-second interval that followed the interval when checking was counted. The activity score quantified the level of nonstereotyped assertive or purposeful behavior such as exploring or grooming. The correlation coefficients of the interrater reliabilities were above .90.

0002-953X/79/03/0311/03/$00.40 © 1979 American Psychiatric Association

The procedure for any single injection study involves two pretreatment observation sessions at 30 and 15 minutes before injection, and four observation sessions at 15, 30, 45, and 60 minutes after injection. During each session, checking was counted for 15 seconds, then general behavior was observed for 15 seconds, and during a third 15-second interval the checking count and the general behavioral observations were recorded. A total of six 45-second cycles were carried out during each observation.

For each observation session, the checking counts for the six 15-second intervals were summed. This yielded a total checking count for each 4.5-minute session, which was compared with the totals for other sessions. The activity scores were tabulated by counting the number of 15-second intervals during an observation session in which the behavior occurred and comparing that number with the number of intervals in which it occurred during other sessions.[1]

Experiment 2: AMPT-L-Dopa-PEA Interaction

In the second experiment, we first established that L-dopa at a dose of 5 mg/kg, administered intraperitoneally (I.P.) in 5 ml of buffered solution, had no observable behavioral effects. Then, 2 hours after pretreatment with AMPT, 125 mg/kg p.o., four monkeys were given L-dopa, 5 mg/kg I.P. Three hours after AMPT pretreatment (1 hour after L-dopa), each animal was given PEA, 75 mg/kg I.M. On a separate day, also after pretreatment with AMPT followed by L-dopa, each animal received saline placebo. The order of treatments was counterbalanced. The pretreatments, injections, and behavioral observations were conducted according to the Experiment 1 schedule.

RESULTS

Experiment 1: AMPT-PEA Interactions

We determined for each treatment the mean change in checking—stereotyped behavior defined as repetitious and nonpurposeful, with abrupt eye and head movements—between observation sessions conducted at 15 minutes before and 15 minutes after I.M. injection of PEA or saline. An analysis of variance was significant for treatment ($F(3,15)=13.32$, $p<.01$) but not for subjects ($F(3, 15)=1.17$, n.s.). Following saline pretreatment, checking increased more after injection of PEA than during other conditions. The mean change in checking for saline-PEA was significantly different ($p<.01$) from the mean changes for AMPT-PEA, saline-saline, and AMPT-saline (Duncan multiple range tests for pairwise comparisons). The mean changes among these last three conditions were not significantly different. These findings are compatible with rat studies in which AMPT blocked PEA stereotypy (1).

[1]Details of scoring, reliabilities, and analyses can be obtained from Dr. Tinklenberg.

We also determined for each treatment condition the mean change in the nonstereotyped activity score between observation sessions conducted before and after injection of PEA or saline. The Duncan test indicated that the mean decrease in nonstereotyped activity for the saline-PEA condition was significantly different from the mean changes for the other treatments ($p<.05$). The mean changes for the other treatment conditions were not significantly different.

During the saline-PEA condition, but not during the other treatments, the monkeys clearly showed other PEA-induced behaviors such as an increase in lip smacking—rapid repetitive opening and closing of the mouth—and an increase in other repetitive, non-goal-directed (stereotyped) behavior such as rocking or chewing-gnashing.

As a control, two of the six animals were pretreated with phenobarbital, 25 mg/kg p.o., and then challenged three hours later with PEA, 75 mg/kg I.M. Although obviously sedated, the animals showed the characteristic PEA effects.

An additional study was done to determine if the inhibitory effects of AMPT on the PEA response were transient. Two monkeys were treated with AMPT, 125 mg/kg p.o. twice a day for four days. On the fourth day, three hours after AMPT pretreatment, the animals received PEA, 75 mg/kg I.M. Neither animal showed PEA effects.

Experiment 2: AMPT-L-Dopa-PEA Interactions

Pretreatment with AMPT followed by L-dopa and then by the challenge injection of PEA produced the characteristic PEA-induced mean change in checking. This L-dopa-restored, PEA-induced checking was significantly different from the change in checking during control (saline placebo) conditions (paired t test, two-tailed, $p<.01$). The mean change in activity score during AMPT-L-dopa-PEA conditions did not differ significantly from the change during AMPT-L-dopa-saline conditions. The AMPT-L-dopa-PEA condition was associated, however, with other characteristic PEA effects such as lip-smacking and other stereotyped behavior.

DISCUSSION

The combined results of Experiments 1 and 2 suggest that AMPT does not directly block all the mechanisms through which the PEA effects are mediated in monkeys. Instead, AMPT attenuation of certain PEA effects in monkeys probably operates through prereceptor mechanisms. This finding is important because AMPT inhibits the enzyme tyrosine hydroxylase, which facilitates the conversion of tyrosine to L-dopa; this conversion is the rate-limiting enzymatic step in the formation of catecholamines. Thus, some of the PEA-induced behavioral changes may require an intact catecholamine pathway or at least require the presence of an adequate pool of L-dopa. Since L-dopa

is easily converted to dopamine, PEA-induced stereotyped behavior in monkeys seems to reflect dopaminergic activity.

The lack of association of checking and nonstereotyped activity changes shown in Experiment 2 cannot be interpreted clearly with the available data. Perhaps the measures of checking are more sensitive; alternatively, checking and other behaviors may be mediated through separate neurochemical pathways. This latter possibility is supported by recent rat studies in which AMPT did not block all PEA effects (15).

The present study indicates that PEA effects are associated with dopaminergic activity. This conclusion is buttressed by reports that different neuroleptics attenuate PEA effects in approximately the same rank order of potency as their ability to block dopamine receptors (11). Our findings are compatible with a dopamine theory of schizophrenia, although at present the necessary supporting evidence is not available (14). Further investigation of PEA and related metabolites may further our understanding of psychiatric disorders.

Gonadotropin Response to Synthetic Gonadotropin Hormone-Releasing Hormone (GnRH) in Heroin Addicts

BY FRANCESCA BRAMBILLA, M.D., LEONARDO RESELE, M.D., DOMENICO DE MAIO, M.D., AND PAOLA NOBILE

To determine whether the pituitary-gonadal deficiency in heroin addicts is related to heroin's effect on the hypothalamus, the authors administered gonadotropin hormone-releasing hormone (GnRH) to 10 male heroin addicts and 5 controls and measured follicle-stimulating hormone (FSH) and luteinizing hormone (LH) response. Basal FSH and LH levels were significantly lower in addicts; after GnRH stimulation the addicts' FSH and LH values increased but not significantly compared to controls. The difference between the two groups' response was highly significant. The authors suggest that heroin causes an incomplete blocking of gonadotropin secretion at the pituitary level, inducing a hypophyseal-gonadal deficiency and a long-lasting depletion of the endogenous releasing factor, which accounts for the reduced response to GnRH.

IN A PREVIOUS STUDY (1) my associates and I observed that male heroin addicts have reduced basal secretion of follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone and that this deficiency is still present 10 days after withdrawal of the drug. These data agree with those of Azizi and associates (2) and Mendelson and associates (3–5) on the testosterone deficiency, which seemed to improve 1 month after withdrawal of the drug. However, in studies by Cushman and associates (6, 7), LH and testosterone levels were normal, with only 12% of the cases showing reduced secretion. Volunteers who were given heroin, either in a single dose or over 10 days, had a significant decrease in testosterone and LH levels, whereas FSH did not seem to be affected (8). Cicero and associates (9) found that heroin addicts had a nonsignificant reduction of testosterone levels, mean volume of ejaculate, and citric acid in the spermatic fluid; a nonsignificant increase in sperm count; and a significant reduction in sperm motility.

Many factors could be responsible for these contrasting results, such as differences in the age of the patients, the daily dose of heroin, the duration of addiction, and previous administration of other drugs of abuse. However, among the addicts hospitalized in our institute for detoxification, we always observe a marked deficiency in the function of the pituitary-gonadal axis; therefore, we thought it worthwhile to study the pituitary response to gonadotropin hormone-releasing hormone (GnRH) stimulation in order to ascertain whether the observed impairment is related to an effect of the drug on the hypothalamus.

METHOD

Sample

The subjects were 10 male heroin addicts, aged 18–28 years, who had a history of addiction to heroin alone that had lasted between 7 months and 7 years. All of the patients had previous histories of intake of other drugs of abuse (amphetamine, LSD, cannabis, morphine) but had been totally off them since they started to use heroin. The daily heroin intake ranged from 300 mg to 3 g of the street preparation (18% pure heroin) and was always taken intravenously.

All of the patients were examined immediately after hospitalization, 8–12 hours after the last heroin intake. All had a normal body build, were without gynecomastia, and had normal masculine hair distribution and normally developed genitalia for their age. All of the patients reported reduced or absent libido and sexual potency. No neurological disorders were found. Three of the subjects had previously had viral hepatitis.

The controls in the study were 5 male patients, matched for age, who were hospitalized for sociofamilial mental deficiency and were endocrinologically normal. All of the addicts and controls gave informed consent.

GnRH Stimulation Test

We used the GnRH stimulation test to evaluate the functioning of the hypothalamo-pituitary axes of our subjects, measuring the FSH and LH responses to the stimulation. The GnRH test was carried out as follows: the patients fasted and rested in bed for at least

8 hours before the test started. They were given 150 μg of synthetic GnRH I.V. as a bolus. Blood samples were drawn through an indwelling catheter inserted in a forearm vein and kept patent by a saline infusion. The samples were taken immediately before the injection of GnRH and 30, 60, 90, and 120 minutes afterward. Because periodic release and circadian rhythms of gonadotropin secretion have been reported (10), all GnRH tests were carried out between 8:00 and 10:30 a.m. Serum FSH and LH were assayed by the radioimmunological methods of Midgley (11, 12) using double-antibody techniques.

The range of LH values was 1.5–25 ng/ml; the interassay error ranged from ±0.97 (±31%) to ±3.05 (±6%), and the intra-assay error ranged from ±1.29 (±42%) to ±5.4 (±10%).

The FSH values ranged from 1 to 17 ng/ml, and the interassay error ranged from ±0.98 (±32%) to ±1.46 (±3%); the intra-assay error ranged from ±1.57 (±5%) to ±2.61 (±5%).

The analysis of variance for a mixed factorial design was done on our data to test the statistical significance of the differences between groups and between times and for the interaction between these two factors. Comparison of averages was done by means of the Scheffé's test (13). The statistical analysis was done with the 5 controls and only 5 of the addicts, selected at random in order to have numerically similar groups. The addicts who were not included in the statistical evaluation showed the same type of response as the patients who were.

The Blachly scale for signs of abstinence (14) was used to check if the patients were showing phenomena related to the withdrawal from heroin.

RESULTS

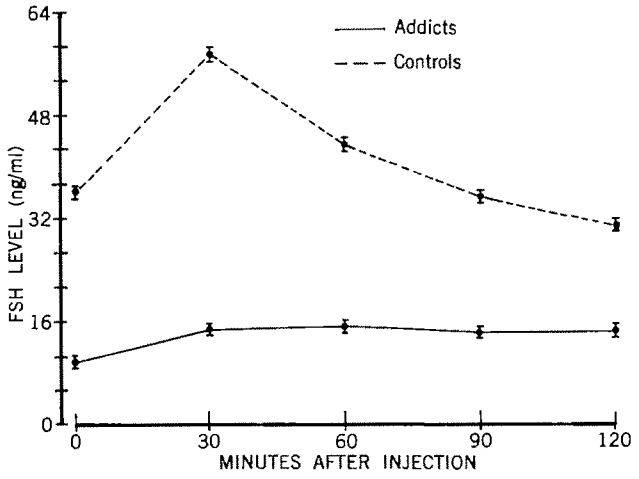
The basal levels of FSH were extremely reduced in all the patients. Stimulation with GnRH induced a mean peak increase of 55.15%. The peak levels occurred between 30 and 60 minutes after injection, with a prevalence of individual peaks at 60 minutes. The increase was still demonstrable after 120 minutes. The controls peaked at 30 minutes, had an average increase of 56.9%, and returned to prestimulation levels at 120 minutes (see figure 1).

The analysis of variance of these data showed a highly significant difference between controls and addicts ($F=111.62$, $p<.01$), both in basal levels and response to stimulation. The difference between times ($F=7.24$, $p<.01$) were both highly significant and indicate that the variations of the means during the test differ according to the subject group. In fact, because of the lower basal FSH levels in addicts, the response to the GnRH test, even though having a percentage of increase equal to that of controls, is not statistically significant in absolute terms.

The basal levels of LH were also very low in all of the patients. GnRH induced a mean peak increase of 147%, with a peak between 30 and 60 minutes after injection. At 120 minutes the increase was still apparent. The controls peaked at 30 minutes; their mean increase was 125% (see figure 2). The analysis of variance of these data showed a highly significant difference between controls and addicts ($F=126.75$, $p<.01$), both in basal levels and response to stimulation, for the same reasons reported for FSH. Differences between times ($F=41.81$) and the interaction between times and groups ($F=25.65$) were highly significant.

The comparisons of both FSH and LH values at baseline and at the 4 subsequent intervals show that in the control group there was a highly significant increase at 30 minutes, followed by a decrease. At 120 minutes, levels reached the pretreatment values. The

FIGURE 1
FSH Response to GnRH in 10 Male Heroin Addicts and 5 Controls



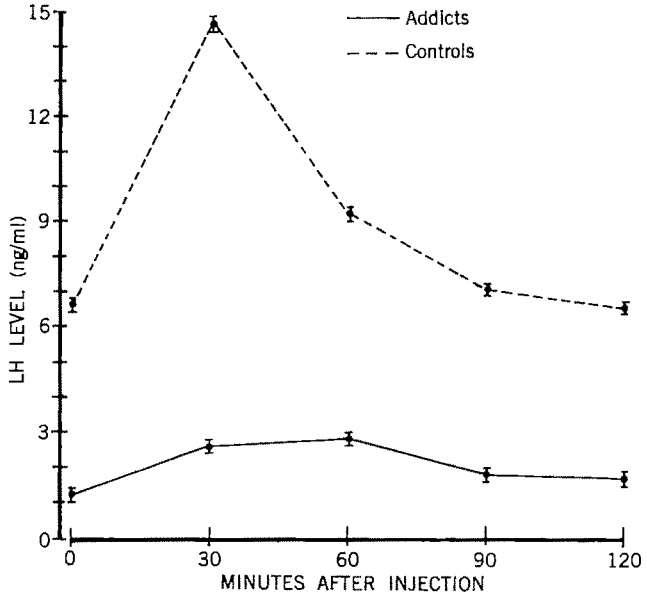


FIGURE 2
LH Response to GnRH in 10 Male Heroin Addicts and 5 Controls

addicts showed no significant difference between times; they had a gradual increase with a peak at 60 minutes and a decrease that had not reached the prestimulation levels after 120 minutes.

The patients did not show significant symptoms of abstinence from heroin.

DISCUSSION AND CONCLUSIONS

Our data again demonstrate that basal LH and FSH levels are greatly reduced in male heroin addicts. GnRH stimulation induced a nonstatistically significant increase in both gonadotropins, with delayed peak times and a slow decrease at 120 minutes. The difference between the response of the addicts and that of the controls was highly significant. The addicts' lower response to GnRH stimulation could have been caused by a primary pituitary impairment (15–20), due to idiopathic pituitary insufficiency, pituitary tumors with decreased levels of basal gonadotropins and an extrasellar expansion, Sheen syndrome, hypothalamopituitary malformations, or acromegaly. We would suggest, therefore, that in these patients heroin acted by blocking the gonadotropin secretion at the pituitary level, thus inducing a hypophyseal-gonadal deficiency. However, even though the GnRH stimulation did not induce a significant response in our subjects, an increase in FSH and LH was observed. This phenomenon suggests that the block of pituitary gonadotropins is not complete.

It has been reported (19–23) that a long-lasting deficiency of endogenous GnRH can induce a reduced and sometimes blunted response to stimulation with the exogenous releasing factor. This phenomenon has been reported in patients suffering from hypogonadotropic-hypogonadism of hypothalamic origin, in hypogonadotropic-hypogonadal patients with anosmia, and in adolescents with delayed puberty. It has been suggested that the degree of prior exposure of the gonadotropes to endogenous GnRH affects both the magnitude and the nature of the FSH and LH response to an acute dose of synthetic releasing factor. In other words, the severity and duration of the hypothalamic deficiency play a role in the type of response to the stimulation by leading to a reduced pituitary reserve of gonadotropimes. In fact, according to Yoshimoto and associates (19), in patients with reduced pituitary response due to prolonged hypothalamic deficiencies, repeated stimulation with GnRH over 7 days normalized the response to the releasing factor.

High levels of androgens reduce the secretion of FSH and LH and the response to GnRH, acting at the hypothalamic levels (20). However, in our patients the testosterone levels were low, so this cannot be the reason for the blunted response. We therefore suggest that the pituitary-gonadal deficiency in our subjects and the reduced response to GnRH stimulation arise from a long-lasting depletion of the endogenous releasing factor related to the heroin addiction. Morphine and its derivatives are known to induce impairments in brain catecholamine levels and turnover in animals (24), although the mechanism of their action has not been completely explained. It is possible that heroin acts at the level of the hypothalamic neurotransmitters in a similar way in humans, thus impairing the secretion of the releasing factor.

The Trial Use of Clozapine for Abnormal Involuntary Movement Disorders

BY ERIC D. CAINE, M.D., RONALD J. POLINSKY, M.D., RONALD KARTZINEL, M.D., AND MICHAEL H. EBERT, M.D.

Twelve patients with abnormal involuntary movement disorders were treated with clozapine in a double-blind, placebo-controlled trial. The cohort consisted of individuals with Gilles de la Tourette's syndrome, Huntington's disease, and atypical persistent dyskinesia that was drug induced. Two subjects were dropped from the protocol due to complications. Two patients with Huntington's disease showed a marked decrease in movements; other individuals obtained no significant therapeutic benefits. Seven of the 10 patients completing the trial experienced moderate or marked side effects.

THE RISK OF persistent, drug-induced dyskinesia or drug-related deterioration of function is a therapeutic dilemma in the treatment of abnormal involuntary movement disorders. Haloperidol is the drug of choice for most patients with Gilles de la Tourette's syndrome (1) and is used frequently for symptom amelioration in individuals with other abnormal involuntary movement disorders. However, patients with Huntington's disease may experience a drug-induced deterioration in function brought on by the neuroleptics used to suppress their choreoathetoid movements (2), while those individuals with severe neuroleptic-induced movement disorders often require palliative treatment with the same agents that caused their dysfunction. Gilles de la Tourette patients may require haloperidol treatment indefinitely; we recently described a 15-year old patient with Gilles de la Tourette's syndrome who had persistent, drug-induced dyskinesia (3).

Clozapine, an antipsychotic dibenzodiazepine, causes few if any extrapyramidal side effects (4). In hopes of finding an effective agent that did not induce persistent dyskinesia, we instituted a clinical trial of clozapine in patients with abnormal involuntary movements. Clozapine demonstrates dopamine receptor blocking properties in vitro (5). The lack of extrapyramidal side effects may be due to its anticholinergic effects (6) or to its apparent augmentation of γ-aminobutyric acid turnover (7). Although clozapine has not led to any known cases of tardive dyskinesia, it is now being withdrawn from the European market, and further research in the United States is being curtailed.[1] The use of clozapine has been associated with fatal agranulocytosis (8).

The authors wish to thank the staff of Ward 2 West, Clinical Center, National Institutes of Health for their cooperation, and D.L. Parrish for assistance in the preparation of this report.

METHOD

Twelve patients participated in a double-blind, crossover trial. Each person was initially assigned to active drug or placebo group by coin toss; subsequently all were crossed over to the other treatment (patient 4 received active treatment only; her symptom

[1]Honigfeld G (Sandoz, Inc): Personal communication, April 19, 1978.

change was compared with baseline tic levels). Placebo and drug phases lasted 4–7 weeks; each individual who completed the study received clozapine in therapeutically significant doses for 3–5 weeks (see table 1). Maximum daily drug intake was determined primarily by the severity of side effects; the maximum dose was 8–10 mg/kg per day (patient 1 was treated at 5 mg/kg per day prior to approval for higher dose levels). Dosage was increased either by a predetermined schedule (by day 10 patients received at least 200 mg) or as each patient tolerated side effects. Dosage of active medication and placebo was controlled by a physician who was not blind to the protocol.

Diagnostic criteria for the 7 Gilles de la Tourette patients included onset of the syndrome before age 14, multiple motor and vocal tics, gradual replacement of old symptoms by new ones, and waxing and waning symptom severity. Six of these patients had previously benefited from treatment with haloperidol. One (patient 5) had been unable to use haloperidol because she had experienced significantly disturbing akathisia. Three patients with Huntington's disease had typical abnormal movements, positive family histories, and changes on computerized tomographic scans consistent with the known neuropathology of the disease. Two patients with atypical drug-induced dyskinesias were diagnosed by positive history of prolonged exposure to phenothiazines, negative family histories of neurological illness, and unremitting abnormal movements for at least 1 year. Both had shown continued progression of abnormal movements while being treated with phenothiazines. Patient 11 had previously been treated unsuccessfully with multiple agents. During the evolution of his present disorder, patient 12 had manifested choreiform hand and toe movements as well as incessant lateral mandibular movements with an intermittent torticollis.

Informed consent was obtained from all patients and from the parents of individuals under 18 years of age.

The Gilles de la Tourette patients were assessed with twice weekly global ratings and with twice weekly tic counts during which a blind rater observed the patient engaged in conversation with another individual for a 5-minute period. These patients were oriented to the study format during a baseline period to lessen their anxiety. A neurologist blind to the protocol twice weekly evaluated the abnormal involuntary movements and general functional ability of the other subjects. A scale of 0–4 (0=no symptoms, 4=debilitating-incapacitating symptoms) was used to rate the subjects.

The significance of changes in each Gilles de la Tourette patient's tic counts was evaluated with Wilcoxon's two-sample rank sum test.

RESULTS

Patient characteristics, maximum dose, therapeutic response, and complications and side effects are presented in table 1. Two subjects (patients 3 and 8) were dropped from the study before significant therapeutic doses were reached. Patient 3 experienced a progressive decrease in his leukocyte count during a 10-day period while on small doses of clozapine (his granulocyte fraction was routinely low before the study). Although this patient's clinical picture was not typical of drug-induced granulocytopenia, clozapine was discontinued as a precautionary measure. His leukocyte count returned to levels greater than 5,000 in about a week. Patient 8 complained of feeling "slightly confused" for 2–3 hours on the day before his total dose was raised from 40 mg to 60 mg. When the dose was increased to 60 mg, he experienced time disorientation, difficulty comprehending statements or instructions, decreased ability to perform routine self-care tasks, and symptomatic orthostatic hypotension with drops in diastolic blood pressure of more than 30 mm Hg. All of his symptoms cleared completely 48 hours after clozapine was discontinued.

One of the subjects with Gilles de la Tourette's syndrome (patient 1) showed a marked reduction in the frequency of simple motor tics. He experienced a decrease from a mean of 51.0 tics (SD=12.5) per 5 minutes to 20.5 tics (SD=14.7, $p<.001$). However, complex manifestations of his disorder were unaffected. These obsessive-compulsive rituals varied synchronously with his other symptoms and were treated effectively with 4 mg of haloperidol daily. The remaining Gilles de la Tourette patients showed no decrease in tic counts at doses of medication that should have had a therapeutic effect in this young population. Four of these patients exhibited a transient exacerbation of symptoms at doses of 50–125 mg. Patients 4 and 6 slept an additional 2–4 hours daily and experienced drowsiness when awake, a side effect also noted by other patients.

The 2 patients with Huntington's disease who reached therapeutic doses showed decreased abnormal movements; both had mild residual symptoms. Patient 9 was extremely sensitive to sedative effects manifested by sleeping an extra 4–5 hours daily. Patient 10 experienced a dramatic increase in abnormal ballistic and choreoathetoid movements after abrupt discontinuation of clozapine. She was given 5 mg of haloperidol daily to control these symptoms.

The patients with atypical drug-induced dyskinesias showed no benefit from clozapine. Patient 12 slept an extra 3–4 hours daily when maintained on his maximum dose.

DISCUSSION

Despite its apparent pharmacological activity clozapine proved clinically ineffective in treating the Gilles de la Tourette patients and the 2 individuals with atypical drug-induced dyskinesias. Two patients with Huntington's disease showed substantially decreased abnormal movements. However, both of them experi-

TABLE 1
Characteristics of 12 Patients Treated with Clozapine for Abnormal Involuntary Movement Disorders

Patient, by Group	Sex	Age (years)	Clinical Features	Maximum Dose (mg)	Therapeutic Response	Complications and Side Effects
Gilles de la Tourette syndrome						
1	M	18	Multiple simple tics (extremities, trunk) and complex ritualistic movements, mild vocal tics	350	Disappearance of most simple tics; rituals unchanged	Symptoms exacerbated at low doses; mild drowsiness
2	M	15	Multiple simple tics (mouth, face, occasional other), moderate to severe coprolalia, moderate vocal tics	425	Mild decrease in motor tics (not statistically significant) without effect on coprolalia	Symptoms exacerbated at low doses; evaluation complicated by benign cyclic neutropenia
3	M	13	Multiple simple tics (face, extremities, trunk); mild coprolalia, moderate vocal tics	150	No change	White blood cell count dropped to 4,100/cu mm (polys=900); clozapine
4	F	12	Multiple simple tics (limbs, trunk) and complex tics (face), moderate coprolalia, severe vocal tics	300	No change	Symptoms exacerbated at low doses; marked somnolence
5	F	19	Multiple mild simple tics (mouth, face), mild coprolalia, mild vocal tics	500	No change	Increased salivation; moderate somnolence
6	F	12	Multiple simple and complex tics (face, trunk, extremities), associated choreoathetoid movements, mild coprolalia, mild vocal tics	375	No change	Symptoms exacerbated at low doses; pulse rate frequently > 130/minute; marked somnolence
7	M	12	Mild simple tics (face) and rare complex tics (extremities), mild coprolalia, mild vocal tics	500	No change	Moderate somnolence
Huntington's disease						
8	M	52	Mild choreoathetoid movement disorder, mild dementia	60	No change	Disorientation, confusion, slurred speech; severe, debilitating orthostatic hypotension
9	M	54	Moderate choreoathetoid movement disorder, mild dementia	200	Decreased abnormal involuntary movements; no change in mentation	Marked somnolence; "less vigor"
10	F	48	Severe choreoathetoid movement disorder (including hemiballismic movements), moderate dementia	500	Decreased abnormal involuntary movements; no change in mentation	Marked "rebound" after cessation of therapy with disabling abnormal involuntary movements, moderate somnolence, frequent hypotension
Drug-induced disorders						
11	F	22	Severe (often disabling) dystonic trunk and limb postures, facial grimacing, blepharospasm, intermittent retrocollis, frequent opisthotonic postures, choreoathetoid movements of extremities, toe walking	425	No change	Mild somnolence
12	M	46	Persistent torticollis (except when supine), hypertrophied neck muscles, involvement of axial muscles (right>left)	300	No change	Marked somnolence

enced clinically significant side effects that compromised their functioning. Although clozapine was useful in treating the symptomatic abnormalities of these 2 patients, further studies were not undertaken due to the emerging evidence about the drug's potential risks. In addition, both patients had less drug-related impairment when taking haloperidol as a maintenance medication.

Simpson and associates (9) have reported the suppression of involuntary movements in adult patients who show the more typical syndrome of persistent drug-induced dyskinesia. They used up to 900 mg of clozapine in treating some individuals. In contrast, the 2 patients with atypical dyskinesia in this study showed no therapeutic response. The finding that 1 Gilles de la Tourette patient showed a reduction in simple tics while the others failed to demonstrate any change may be indicative of heterogeneous pathophysiologies in this syndrome.[2]

All but 1 of the Gilles de la Tourette patients in this trial had therapeutic responses to haloperidol. Similarly, haloperidol lessens many of the movements of patients with Huntington's disease and persistent drug-induced dyskinesia. Both haloperidol and clozapine possess antipsychotic properties. However, data from this study suggest that while clozapine suppresses some kinds of abnormal involuntary movements, it is ineffective in treating others. When one is studying the pathophysiology of diseases of the central nervous system, it will be essential to carefully consider assumptions about neurochemical mechanisms based principally on the action of diffusely acting pharmacological agents.

Complex Partial and Pseudoseizure Disorders

BY RONALD A. REMICK, M.D., AND JOHN A. WADA, M.D.

The differentiation of ictal and nonictal seizure disorders is difficult, particularly in patients suffering from partial seizures with complex symptomatology. The authors state that observation of a patient's habitual seizure during EEG recording is the ideal diagnostic tool and describe their method of seizure activation with sphenoidal electrodes and simultaneous audiovisual monitoring. They emphasize the necessity for early, aggressive treatment of both ictal and nonictal seizure disorders, point out risks to the patient if the incorrect diagnosis is made, and urge further cooperation between psychiatrists and neurologists in this borderland area.

SEIZURE ACTIVATION with sphenoidal EEG electrodes and simultaneous audiovisual monitoring developed as an aid in evaluating patients who have a seizure disorder that has not responded to medication and who are being assessed for possible neurosurgical intervention (1). This procedure is also of significant diag-

Received Jan. 30, 1978; revised June 2, 1978; accepted July 18, 1978.

nostic assistance in differentiating the ictal and nonictal complaints of patients with seizure disorders, particularly partial seizures with complex symptomatology.

The diagnosis of complex partial seizures, formerly known as temporal lobe epilepsy or psychomotor epilepsy (2), is based on clinical symptomatology, and this diagnosis is supported by the presence of specific electroencephalographic abnormalities. Only the lateral convexity of the cerebral hemispheric surface is accessible to traditional scalp EEG tracings, which has led to the development of a method for electrographic monitoring of the basal cerebral surface. This latter procedure significantly adds to the evaluation and diagnostic assessment of complex partial seizures, as surface EEG monitoring often fails to record irritative disturbances in the more mesial and inferior surfaces of the cerebral hemispheres. Nasopharyngeal electrodes are relatively easy to apply but are subject to several disadvantages (3). Monitoring through sphenoidal electrodes is subject to less artifactual contamination and is preferred for identification of abnormalities, particularly in the anteromesial aspects of the temporal lobes (4, 5).

When focal cerebral abnormalities are suspected, as in a patient with complex partial seizures, seizure activation techniques may provide information as to the site of onset of the habitual seizure. Although traditional activation techniques such as hyperventilation, photic stimulation, and sleep are part of the routine evaluation of patients with a seizure disorder, often pharmacological activation is necessary for further diagnostic clarification. The observation of a patient's habitual seizure during EEG recording is the ideal for diagnosis and treatment. This is essential for those patients considered for neurosurgical treatment, and it greatly assists the diagnosis and management of patients with complicated clinical pictures.

The procedure we use in selected cases is as follows. Under local anesthetic bilateral sphenoidal electrodes are inserted transcutaneously under the zygomatic arch to rest near the foramen ovale (5). Fine wire electrodes are then inserted through the needle electrode, the electrode is removed, and the wire is firmly fixed to the skin with adhesive tape. By use of a split screen in our audiovisual studio, simultaneous monitoring of a 16-channel EEG and the patient occurs throughout the procedure.

An intravenous catheter is inserted and a "cocktail" of pentylenetetrazole (Metrazole), 200 mg in 2 cc (10%), and bemegride (Megimide), 90 mg in 18 cc (0.5%), is infused as follows: 5 cc initially, followed by 1 cc every 30 seconds until activation occurs. Positive activation is an abnormal EEG discharge frequently associated with clinical seizure manifestations that is identical to the patient's described pattern of habitual seizure. When activation occurs the procedure is rapidly terminated by intravenous diazepam (10–20 mg).

We believe this procedure may be of great value to clinicians who have cases in which the differential diagnosis between seizure disorder and conversion symptoms or pseudoseizures is difficult.

CASE REPORT

Ms. A, a 24-year-old woman with an 8-year history of seizures and 9 previous psychiatric hospitalizations related to disturbed interpersonal relationships and impulsive behavior, was readmitted to the psychiatric hospital for further assessment of her seizure disorder. Her "fits" were characterized by voices becoming distant; visual illusions such as faces becoming distorted, depersonalization, and "dreamy" sensations; and feelings of nervousness and panic. They had increased to twice daily despite the regular ingestion of anticonvulsant medicines for 2 years.

Ms. A's seizures began when she was 16 after she experienced a traumatic head injury and lost consciousness. She was placed on anticonvulsants, and her seizures decreased in intensity and stopped completely 2 years later. The seizures recurred when she was 22 years old. An electroencephalogram at this time was minimally abnormal. A sphenoidal EEG revealed slow activity in the left temporal region. It was felt that many of Ms. A's complaints were consistent with a complex partial seizure disorder involving the anteromesial portion of the left temporal lobe. Two years of anticonvulsant treatment had not successfully controlled her seizures.

Ms. A was the second of 3 children. Her parents were alcoholics and had separated when she was 9 years old. Her mother had some form of epilepsy, but at times Ms. A was not sure whether in fact her mother was "faking it." Ms. A began to live with her father when she was 14 and was sexually molested by him when she was 16. This was also the time she began to have seizures. Over the next few years she moved back and forth between her mother and father, until she became pregnant by a man she subsequently married.

Ms. A's relationship with her husband was stormy. They were married for 5 years, during which Ms. A had 8 psychiatric hospitalizations after suicide attempts that seemed to occur at times of severe marital strife.

On admission, Ms. A was detached but clear in her speech. There were no abnormalities in her mood, mental content, or sensorium. Physical and neurological examination was normal. During her hospitalization, a seizure activation with sphenoidal electrodes and audiovisual monitoring was obtained. After 14 cc of the pentylenetetrazole-bemegride cocktail was infused, Ms. A suddenly tensed up, her face became flushed, and tears welled up in her eyes. Her mouth became distorted, and her verbal responses to inquiry became extremely unclear. She stated that she was experiencing perceptual alterations so that things did not appear real around her and voices sounded far away. This state lasted well over 2 minutes and during this time the EEG showed no focal or lateralizing features. Throughout the monitoring there were no specific electrographic events that were related temporally to Ms. A's clinical subjective experiences. She eventually received 70 cc of the cocktail, a dose almost 3 times that required to activate habitual seizures in our patient population. Ms. A stated that she had in fact had her habitual seizure during this procedure.

We discussed the results with Ms. A and explained that she had an electrographic abnormality but that her clinical subjective phenomena did not correlate with the EEG findings. We suggested that she explore her difficulties further with psychiatric assistance, and during the last year she and

her husband have continued in outpatient conjoint psychotherapy. There has been a dramatic reduction in the number of her seizures, even with reduced intake of her anticonvulsant medicines.

DISCUSSION

The purpose of this report is to make others aware of a procedure that may help to differentiate ictal and nonictal symptomatology. We also hope this report will call psychiatrists' attention to complex partial seizures, a disorder in the borderland between neurology and psychiatry.

Although conversion symptoms are not seen by psychiatrists as frequently today as they were in the past, they are still a common occurrence on neurology and general medicine wards. Differentiating complex partial seizures from pseudoseizures can be quite difficult and requires the physician to have a thorough knowledge of the clinical manifestations of seizure disorders (6, 7). That patients with psychiatric disorders have a high percentage of EEG abnormalities adds to the diagnostic dilemma (8, 9).

It is not unusual to see a case like the one described above in clinical practice. Ms. A had an episodic behavioral pattern, nonspecific EEG abnormalities, and a possible family history of a seizure disorder. Her characterological problems were consistent with the observation that patients with seizure disorders, particularly complex partial seizures, frequently have psychiatric disabilities (10, 11).

Did Ms. A have an ictal event with no electrographic correlates? If more midline or deeper brain structures initiated the seizure, EEG abnormalities may not have been recorded, but the clinical pattern would have been quite different. The extremely large dose of convulsant medicine would certainly produce EEG changes and/or induce a generalized convulsion in a patient with a genuine seizure disorder. A review of our patient's records showed nonspecific EEG changes only, and her subsequent positive response to psychotherapy argues for a pseudoseizure disorder.

The separation and clear identification of seizure disorder and psychiatric disorder is most important because the treatments for each are quite different, and early intervention is paramount in both illnesses. We are becoming aware through kindling studies (12–14) that untreated repetitive intermittent electrical stimulation of subcortical structures may lead to focal seizures and, eventually, generalized convulsions. These generalized convulsions are the result of an electrical stimulation that was previously subthreshold. Thus, not recognizing a seizure disorder and failing to institute prompt treatment may result in more widespread irritative cerebral activity, which will be more difficult to treat later. Because patients with complex partial seizures may first consult a psychiatrist, it is imperative that psychiatrists be familiar with this disorder.

The other side of the coin applies as well. Clinical theory would suggest that some types of psychopathology become harder to eradicate the longer they are left untreated (15). Maladaptive patterns become entrenched, and patients become less susceptible to change over time. It would seem that patients would be more accessible to change with early intervention and treatment, and this point is emphasized in the preventive psychiatry literature.

Other difficulties may result if a seizure disorder and psychopathology are not separated. Anticonvulsant drugs, like psychotropic medications, are not innocuous agents, and serious side effects can occur with long-term use (16). Thus, they should only be used when clearly indicated. Another problem would be the demoralization of patients treated for an emotional problem when a physical disorder is the root of the problem. In later reports we will document how, in fact, psychiatric treatment caused an iatrogenic psychiatric disorder in patients with complex partial seizures.

We strongly believe that separating the ictal from the nonictal can only be done when psychiatrists and neurologists work closely together. To do this, the neurologist must be more cognizant of just what a psychiatrist can and cannot do. The patient described had always had various functional labels during her past treatments in addition to her neurological disorder, but it was not until a joint approach was undertaken that meaningful progress was made.

Likewise, psychiatrists must be more aware of what neurologists can offer. A good example is in the field of electroencephalography. A normal EEG does not rule out a seizure disorder. If a clinician suspects complex partial seizures, he or she should pursue this hunch vigorously. This would mean obtaining, in addition to a routine EEG, a collateral history, a sleep electroencephalogram, perhaps sphenoidal and/or nasopharyngeal monitoring, and at times a procedure to monitor the habitual seizure. Although a normal EEG does not exclude a seizure disorder, an abnormal one does not mean epilepsy is present. Electrographic abnormalities are frequent in psychiatric populations (17), but these patterns are usually nonspecific. The diagnosis of a seizure disorder should be based on clinical symptoms, and the EEG should only assist in the diagnosis.

We believe that the seizure activation procedure described is one neurological development that may be helpful to psychiatrists. Sphenoidal electrodes and activation techniques have been shown to be both safe and reliable in the hands of clinicians familiar with these techniques (18). We have outlined the benefits of the correct diagnosis and treatment and the risks to the patient if the incorrect diagnosis is made.

Schizophrenic Patients and Schneiderian First-Rank Symptoms

BY MOSES PREISER, PH.D., AND WILLIAM JEFFREY, M.D.

Differences between schizophrenic patients with Schneiderian first-rank symptoms (FRS) and those without FRS at the time of hospitalization indicated FRS were associated with behavior consistent with feelings of passivity and helplessness. The two groups responded equally well to treatment in a therapeutic community. Findings support the contention that FRS are not pathognomonic or prognostic in schizophrenia.

SCHNEIDER (1) has described 11 first-rank symptoms (FRS), which he suggests are pathognomonic of schizophrenia when toxic or organic etiology has been ruled out. These symptoms have been used diagnostically in Europe and have recently been the focus of research efforts in the United States. The FRS are the presence of delusional perceptions (normal perceptions given a sudden and idiosyncratic interpretation that cannot be understood in the general context of the patient's ideation); three forms of auditory hallucinations (voices speaking one's thoughts out loud, voices arguing, and voices commenting on one's actions); and seven types of delusions (sensations or other bodily changes imposed by an outside influence, thoughts taken away from one's mind, thoughts inserted into one's mind, one's thoughts being broadcast, one's emotions not being one's own, overwhelming impulses for action imposed by an external source, and actions not one's own).

An initial optimism in the use of FRS as definitive indicators of schizophrenia (2, 3) has lessened, and current studies show their prevalence but not pathognomonicity in schizophrenia (4–8). Because these

symptoms have been proposed as pathognomonic of schizophrenia, it has been assumed they represent severe psychopathology; this assumption has led to evaluations of their prognostic value.

Taylor (9) first presented data suggesting that the presence of FRS in schizophrenia indicates poor prognosis, but after a further study (10) he determined there was no difference in acute treatment response (measured on a 0–7 scale) once a definite, not presumptive, schizophrenic diagnosis was established.

McCabe (11) felt schizophrenics with FRS often fell in the group of schizophrenics considered to have poor prognosis. Results from the rigorous Washington Field Research Center of the International Pilot Study of Schizophrenia showed no poorer prognosis for schizophrenics with FRS than for those without after 2 and after 5 years (12, 13).

There have been attempts (14, 15) to determine which patients do least well (and who might even react adversely) on intensive short-term treatment units. The question of course and outcome for schizophrenics with FRS on such units has not been fully explored. If schizophrenics with FRS have more severe psychopathology and perhaps psychopathology less amenable to treatment than schizophrenics without FRS, channeling them to less intensive treatment programs might be more effective use of costly treatment.

The present study was undertaken to explore two questions. 1) Do schizophrenics with FRS have more observable pathologic behavior than schizophrenics without FRS? 2) Do schizophrenics with FRS have a poorer response to an intensive short-term treatment program than schizophrenics without FRS?

METHOD

The study was conducted on a 24-bed therapeutic community ward in a large municipal hospital. The patients participated in self-government, and the various therapeutic modalities on the ward included individual and group psychotherapy, psychodrama, and a variety of task-oriented activities. The majority of the patients were medicated.

In most instances, patients were referred from the acute wards of the psychiatric hospital. These were patients who were judged to need hospitalization of at least 2 weeks' duration and to have the potential to profit from the intensive therapeutic experience offered. Maximum stay on the ward was 3 months and the average stay was 6 weeks. More detailed description of the ward can be found in reports by Winston and Papernik (16) and Jeffrey and associates (17).

Evaluations

During a 6-month period all patients admitted to the ward were evaluated in the following ways:

1. One of two nurses completed the Psychotic Inpatient Profile (18) for each patient on admission to the ward and again at discharge. The Psychotic Inpatient Profile (PIP) is an instrument consisting of 74 statements describing manifest ward behaviors and 24 statements describing patients' self-reports. Nurses' ratings of each statement's applicability to a given patient are summed up to yield 12 subscores, each of which reflects a particular dimension of manifest psychotic behavior. Specifically, the subscores reflect excitement, hostile belligerence, paranoid projection, anxious depression, motor retardation, seclusiveness, inability or unwillingness to care for oneself, psychotic thought or motor disorganization, grandiosity, perceptual distortion, depressive mood, and disorientation.

2. When the patients were admitted to the ward and again on discharge, the recreation therapist evaluated them on a 5-point social participation scale that measured a combination of frequency and quality of social interactions.[1]

3. On admission and again at discharge, each patient was evaluated by one of two group therapists[2] on a 5-point scale measuring degree of impairment of functioning (i.e., ability to carry out the basic responsibilities of everyday life.)[1]

4. Each patient's individual therapist evaluated the patient's symptomatology for the presence or absence of first-rank symptoms as enumerated and defined by Mellor (3), and this assessment was reviewed and corroborated by a senior attending psychiatrist.

5. Discharge diagnosis was determined by the individual therapist in consultation with the attending supervisor using Bleulerian (20) and/or ego function (21) criteria, as is customary on the ward.

Evaluations 1, 2, and 3 of the schizophrenic patients were subjected to statistical analyses comparing those with first-rank Schneiderian symptoms (FRS-positive) and those without such symptoms (FRS-negative). The social participation and impairment of functioning measures were subjected to a chi-square analysis. The PIP data were analyzed by one-way ANOVAs comparing the FRS-positive to the FRS-negative groups on each of the 12 subscores at the time of admission. Discharge subscores were subjected to an analysis of covariance in which the respective admission subscores were used as covariates to ensure that significant differences found would reflect response to the treatment program rather than possible preexisting differences between the groups.

RESULTS

Of the 88 patients admitted to the ward over a 6-month period, 52 were given a discharge diagnosis of

[1]The 5 rating statements were identical to those published by Sanders and associates (19, pp. 252, 255). However, in our study the ratings were simply assigned numbers from 1 to 5, unlike the more complicated system used by those authors.

[2]On an independent sample of patients, an interrater reliability of .83 was obtained.

schizophrenia. Of these 52, 25 exhibited at least one Schneiderian first-rank symptom, and 27 exhibited none. Five patients not diagnosed schizophrenic also exhibited FRS. These patients were not included in any of the subsequent analyses reported in this study. The FRS-positive and FRS-negative groups were similar in their demographic composition. The mean age was 25.6 years for the FRS-positive group and 23.3 for the FRS-negative group ($t=1.36$; $p>.10$). The number of black, white, and Hispanic patients was 14, 7, and 4, respectively, in the FRS-positive group and 17, 8, and 2, respectively, in the FRS-negative group ($\chi^2=.95$; $p>.10$). There were 13 males and 12 females in the FRS-positive group and 14 males and 13 females in the FRS-negative group ($\chi^2=.01$, n.s.).

All discharges that occurred before the date agreed on between patient and therapist were considered premature. In the FRS-positive group 4 patients left prematurely and in the FRS-negative group 6 left prematurely, a nonsignificant difference ($\chi^2=.25$; $p>.05$). The groups did not differ significantly in their length of stay (premature discharges were excluded in this analysis); means were 59.6 days and 56.7 days for FRS-positive and FRS-negative groups, respectively ($t=.17$, n.s.).

Evaluations

1. Analysis of variance of the patient's 12 PIP scores at the time of admission yielded two subscale scores that differed significantly. The patients in the FRS-positive group were evaluated significantly higher on the anxious depression subscale ($F(1, 50)=4.02$; $p<.05$) and lower on the excitement subscale ($F(1, 50)=4.33$; $p<.05$). Because it seemed paradoxical that one group should be both more agitated (as seemed implicit in the first finding) and less excited (as suggested by the second finding), individual analyses were run for the items in each scale. The items that significantly differentiated the two groups were, in fact, not contradictory. Thus, from the anxious depression subscale, the FRS-positive group scored significantly higher on the following items (including differences at $p<.10$): number 18, "looks worried or nervous" ($t=3.54$; $p<.01$); number 9, "shows real sadness in face and posture" ($t=2.37$; $p<.05$); number 42, "appears frightened" ($t=1.77$; $p<.10$); number 29, "looks tired and 'all worn out' " ($t=1.70$; $p<.10$). From the excitement subscale the FRS-positive group scored lower on the following items: number 14, "tries to attract attention to self; shows off" ($t=1.97$; $p<.10$); number 23, "jokes, talks, or laughs excitedly; seems high" ($t=1.79$; $p<.10$); number 73, "acts superior to other patients (conceited and boastful)" ($t=1.79$; $p<.10$); number 59, "shouts and yells" ($t=1.75$; $p<.10$). Analyses of the PIP evaluations at the time of discharge for the 12 subscales yielded no significant differences.

2. Comparing the evaluations for the two groups on the social participation scale yielded a significant difference at the time of admission ($\chi^2=10.30$; $p<.05$). The modal rating for the FRS-positive group on admission was number 4: "Prefers to be by himself. Actively avoids contact with others whenever possible but will respond when pressed. Has no recognizable friendships. May have close relationships with family members, but on examination these prove to be pathological (e.g., excessive dependence, etc.). Interaction is infrequent or frequent but inappropriate." The modal rating for the FRS-negative group on admission was number 3: "Participates to a limited extent. Tends to keep his distance from others but will respond appropriately at a superficial level. Has few (if any) genuine friendships, tends not to become deeply involved. Contacts are neither numerous nor frequent. Very few group contacts. Neither seeks nor actively avoids contact with others. Does not initiate conversations." No significant differences between the groups' ratings on this measure were found at the time of discharge.

3. Comparing the evaluations for the two groups on the impairment of functioning scale yielded no significant differences either at the time of admission ($\chi^2=3.18$; $p>.10$) or at the time of discharge ($\chi^2=1.54$; $p>.10$).

Additional Data

In conjunction with another study on the same ward, additional data regarding rehospitalization within 6 months of discharge was obtained for 37 of the patients included in the present study. In the FRS-positive group, 7 of 19 required rehospitalization within 6 months of discharge, and in the FRS-negative group, 6 of 18 required rehospitalization within the same period (1 of the 6 had committed suicide). The difference in rehospitalization rates between the two groups was not significant ($\chi^2=.27$; n.s.).

CONCLUSIONS

Differences found between a group of schizophrenics displaying Schneiderian first-rank symptoms and those without such symptoms were evident only at the time of admission. These differences included the greater degree of worry, sadness, fright, and tiredness evident in the behavior of the FRS-positive group as opposed to the more boisterous and grandiose behavior displayed by the FRS-negative group (as observed and rated by the nursing staff). These differences in behavior may reflect a more intense experience of helplessness and passivity that would be consistent with a concept of more severe ego-boundary dissolution implicit in many of the first-rank symptoms (forced actions, thoughts broadcasted, etc). With the amelioration of symptoms and with recompensation (which both groups were equally able to achieve), significant differences between the groups could no longer be found on any behavioral dimensions measured.

The differences found at the time of admission on the social participation scale seem compatible with the above mentioned behavioral differences; the more

worried and frightened FRS-positive group tended to be more socially withdrawn, and the more boisterous and grandiose FRS-negative group tended to have impaired but more frequent social interactions.

On a variety of measures of course and outcome (length of hospital stay, degree of recovery measured globally as well as in a number of specific areas of functioning, and need for rehospitalization within 6 months) the data corroborate and extend previous findings that among schizophrenics whose diagnosis is established the presence of Schneiderian first-rank symptoms does not indicate poorer response to treatment. Therefore, the presence of first-rank symptoms should not be used as a basis for excluding schizophrenic patients from intensive treatment because of apprehension of poor outcome.

Lastly, 5 of the patients in the overall population on the ward at the time of the study exhibited Schneiderian symptoms but were not diagnosed schizophrenic. These patients represented 9% of the patients with Schneiderian symptoms and 14% of the patients not diagnosed schizophrenic. These percentages are consonant with most previous findings and indicate that first-rank symptoms are prevalent in but not pathognomic of schizophrenia.

Patient Access to Medical Records on a Psychiatric Inpatient Unit

BY EUGENE J. STEIN, PH.D., RONALD L. FUREDY, M.D., MARY JANE SIMONTON, R.N., AND CYNTHIA H. NEUFFER, M.S.W.

The authors studied the effects of patient access to medical records during hospitalization in a psychiatric unit of a community general hospital. Questionnaires were completed by about 20 staff and 88 patients, and records were compared with those from an earlier period to note any changes in the written record. Patients reported feeling better informed and more involved in their treatment, and staff said that they became more thoughtful about their notes in the chart. The availability of staff seems crucial to this process and facilitates the working alliance.

ALTHOUGH IT has been suggested that patient access to medical records might result in better informed and more actively involved patients, rarely do patients have free access to their medical records during hospitalization (1). Issues such as privacy, confidentiality, costs, accountability, efficiency, patients' rights, and malpractice have fostered a lack of mutual trust in the doctor-patient relationship. However, in psychiatry this trustful relationship, the working alliance, is considered the very basis of therapy. Redlich and Mollica (2), for example, have implied that psychiatrists are ethically "bound by an obligation" to establish such a "partnership." They go on to suggest that "informed consent is the basis of all psychiatric intervention . . ." Shenkin and Warner (3) have suggested, in effect, that patient access to the medical record might result in the patient's being better informed and a more active partner in treatment. These authors implied that patient access to the record would improve the physician-patient relationship, with increased satisfaction for both parties.

In 1973 Shenkin and Warner proposed legislation to require that a complete and unexpurgated copy of all medical records, both inpatient and outpatient, be issued routinely and automatically to patients as soon as the services provided are recorded" (3, p. 688). They felt this proposal might alleviate four serious problems—poor quality of care, unsatisfactory physician-patient relationships, lack of continuity, and excessive bureaucracy—that have been associated with "widespread" dissatisfaction with the functioning of the medical care system. Although Shenkin and Warner were impressed by the generally favorable response to their proposal (4), a search of the literature suggests that few facilities have been willing to put the proposal into practice, and in the more popular medical literature, one finds articles such as "The Patient's Chart Is None of the Patient's Business" (5).

Despite considerable armchair speculation of this sort, our review of the literature revealed no studies of psychiatric patients having access to their records and only two reports in other specialties (6, 7).

The staff of a psychiatric inpatient unit of a community general hospital disagreed as to whether patients should be able to read their records while in the hospital. Some argued that patients would not understand the information or would in some way be harmed by it. Some felt that it would be very difficult to communicate information such as diagnoses. Others felt that patients had a right to know what was being written about them and that openly available records would be more consistent with the treatment philosophy of a therapeutic community, which emphasizes openness and responsibility. The staff agreed to permit patients access to their records on a trial basis provided that the new policy's impact on patient care was evaluated. An interdisciplinary task force consisting of the authors was appointed to study patient access to medical records.

METHOD

Every evening the entire patient group met, and each patient was given his or her current medical record to read. At least one nursing staff member was available to help the patients understand terminology and decipher handwriting. The record was available only to the individual patient and the staff; it was available to the patient for informal review throughout the day, except during doctors' rounds. Family members were not allowed to read the medical records, and pa-

tients were not allowed to read each other's records. This procedure was followed for a period of approximately five months, during which the following surveys were done.

1. Patient questionnaire. The questionnaire was given to 102 of the 106 patients consecutively admitted to the psychiatric inpatient unit of the hospital. This was usually done by the psychiatric social worker one to two days before discharge. Of the 102 patients, 4 were discharged against medical advice and 5 were transferred to other units without completing the questionnaire. Three patients were unable to complete the questionnaire because of intellectual or language difficulties, and 2 refused to participate in the study. Thus 86% (N=88) of the patients who received the questionnaire completed it.

2. Staff questionnaire. Twenty staff members of the inpatient unit completed this questionnaire during the first month that patients had access to their records. Nineteen staff members completed the questionnaire when it was readministered during the fifth month of the study.

3. Record review. Two random samples of 25 medical records each were drawn from the 1975 period when patients had daily access to their records and from a comparable period in 1973–1974 when patients did not have such access. Two nursing students performed part of the review, and we performed the other part. We had an average interrater agreement of 93% and the nurses, 92%.

RESULTS

Patient Response[1]

The vast majority of the patients (77, or 92%) were in favor of open medical records. They felt that access to their medical records during hospitalization helped them to better understand their problems (75, or 86%) and take a more active role in their treatment (72, or 85%). To a lesser extent, most of the patients said that access to their records afforded them an opportunity to correct inaccurate information (54, or 68%). Most patients felt comfortable about reading their records (72, or 84%), and a majority felt more self-confident as a result (60, or 71%). However, a substantial minority felt more pessimistic after reading their records (26, or 32%) and roughly half of the patients said they were upset by some of what they read (43, or 51%). Although the patients felt better informed, they did not always like what they read.

Although half of the patients were upset by some statements, very few felt that the staff had made untrue statements about them (16, or 19%) or had avoided noting certain things about them because of the open records (9, or 11%). In fact, roughly two-thirds of the patients (55, or 66%) felt that the staff became more accurate in what they wrote in the records. Patients were equally divided on the question of whether the staff became more respectful (41, or 51%). Slightly more than half of the patients thought open records had some impact on what the staff wrote (47, or 56%), and the vast majority of the patients thought that open records made some difference in their treatment (73, or 86%). Few feared for the confidentiality of their records (10, or 12%).

Staff Response

Ninety percent of the staff (N=18) were favorably disposed to open medical records after initial exposure. After approximately five months of experience with daily patient access to records, 79% (N=15) still wanted to continue this policy. The vast majority of the staff said they were comfortable with open records (19, or 95%) and thought this was a useful therapeutic tool (17, or 89%). Initially, 35% (N=7) thought open records had little impact; however, after more exposure only 11% (N=2) came to this conclusion. Most felt that they became more accurate in their observations (13, or 68%) and more thoughtful in their conclusions (about 15, or 79%) because of open records. A sizable proportion did not record information that they felt would upset the patient (4, or 20% initially and 11, or 58% finally), and they found other ways to communicate this information to staff, usually verbally during rounds and in shift-to-shift reports. It is important to note that this information pertained not to diagnosis but to intimate details of the patient's personal life. In addition, an increased number of staff (6, or 33%) reported that they had to seek information from other sources because of open medical records. Despite the tendency for many staff to omit certain information, only 26% overall (N=5) reported that they were less likely to diagnose a patient as psychotic because of open records.

Sixty-five percent of the staff (N=13) thought that open records helped the treatment of most patients, and this proportion increased to 70% (N=14) after five months. Eighty percent (N=16) felt that at least a few patients were helped by open records, and none of the staff felt that open records were generally harmful to patients even after five months of experience with this policy. However, 26% (N=5) knew of at least 1 patient who was harmed by open records. We do not know how many of the patients who participated in this study were thought to have been harmed by open records, but we suspect that there were only 1 or 2. Despite these concerns and changes in the pattern of staff communication, 63% of the staff (N=12) concluded that open records made the chart a more valuable clinical document.

Chart Review

The number of notations of disruptive behavior doubled with open records (mean averages of .68 and 1.55, $p<.10$, t test). The number of cross-outs and erasures appeared to decrease, and the number labeled "error"

[1]Tables presenting the results of the patient questionnaire, staff questionnaire, and the record review have appeared elsewhere (8).

or initialed by a staff member doubled with open records (averages of .52 and 1.00, $p<.05$). No change was detected in the rating of the physician's description of the patient's history and physical examination. These results appear to be consistent with results of the questionnaires.

The increase in the number of cross-outs and erasures labeled "error" and the decrease in the number of cross-outs and erasures not labeled suggest that the staff may well have become more thoughtful and that the patients may indeed have been able to correct some inaccuracies. The increase in the number of notations of disruptive behavior may account for some of the upset feelings noted in patient questionnaires.

DISCUSSION

The results of this study are strikingly similar to those of Golodetz and associates (7) and Bouchard and associates (6), who gave sections of the problem-oriented record to rehabilitation patients. The methodology is also similar. Bouchard and associates found that "in the vast majority patients are reassured and motivated by reviewing their own health care data. Ninety-seven percent of patients feel relieved and less anxious after reviewing their own records" (6, p. 46). Golodetz and associates found that "patients were generally comfortable about reading the record, found it educational and appreciated the trust implied. No substantial difficulties arose. Few records were expurgated" (7, p. 79). We found that even though patients were sometimes upset by what they read, they were generally comfortable with reading their records and felt better informed and more involved in their treatment. The staff felt that patient access to medical records was therapeutic. The staff tended to omit certain details from the record, but they also became more accurate and thoughtful in what they wrote, and the patients had a chance to correct inaccuracies.

All three studies suggest positive benefits including enhanced patients' rights, improved treatment, and improved patient-staff relationships. It appears that few patients were harmed by this policy, and the benefits seem to outweigh the costs. We are aware of no study showing a significant negative impact of patient access to the medical record. One must caution that all three studies took place in settings where the team approach was used. The policy of open medical records is not without difficulties. Specifically, it seems crucial that availability of the record be accompanied by availability of the staff to discuss the record. This process, in itself, appears to be useful in facilitating a working alliance between patient and staff.

Response of Patients to Participation in Psychiatry Board Examinations

BY HAROLD ROSEN, M.D., LEON B. COHEN, PH.D., LESLIE SCHWARTZ, M.D., AND JOSEPH N. DIGIACOMO, M.D.

The patient who volunteers to be a subject for Part II of the certifying examination in psychiatry and neurology is an indispensable but surprisingly invisible participant in a highly controversial process. A survey of the attitudes of 78 patients toward this experience revealed that although they experienced a significant degree of stress, the overwhelming majority viewed their participation in strongly positive terms. The patient's loyalty to the host institution and the manner in which the patient is prepared for the experience appear to be the major factors in determining a positive outcome.

THE PATIENT WHO volunteers to be a subject for the American Board of Psychiatry and Neurology (ABPN) Part II examination (the oral portion) is an indispensable but surprisingly invisible participant in a dramatic and increasingly controversial process. Although the impact of this experience on the candidate has been the subject of much debate (1–3), the impact on the patient has received little attention in the psychiatric literature. To our knowledge the only article in the literature consists of an unreplicated study published in 1972 by Eveloff and McCreary (4), in which the authors found that a middle-class, relatively well-educated group of patients suffered no serious consequences as a result of their participation as Board subjects and tended to view their experience as "slightly positive." Given the increasing emphasis on patients' rights and the rapidly escalating criticism of the value of the Part II examination (5), further investigation of this issue appeared warranted in order to ensure that the examination process was not detrimental to the well-being of the patient.

This report will present the findings of a survey of patients' attitudes toward their participation in the present ABPN oral examination procedure. It is our hope that these findings will prove useful in clarifying one of the many complex issues that must be resolved in order to determine the future format of the certification process (6).

METHOD

The subjects for this study consisted of 78 randomly selected male patients between the ages of 21 and 65 who were on the active treatment roster of a Veterans Administration health care facility and who volunteered to participate in the patient interview section of the Part II examination held on October 17 and 18, 1977. The overwhelming majority of the patients were high-school-educated, blue-collar workers who had received a primary diagnosis of schizophrenia, affective disorder, or alcohol addiction.

Each patient, with the exception of 7 patients on an inpatient research unit, was contacted by a member of the organizing committee approximately 12 weeks before the examination and given an explanation of the examination procedure that stressed the benefit to the candidate and psychiatric profession rather than to the patient. All patients were asked to participate in a minimum of 2 examining sessions. If they agreed, they were asked to sign a statement of consent and to select the times most convenient for them. Of the original 83 patients, 5 refused to participate; the most frequent explanation was an inability to take time off from work. Potential subjects were then contacted at 4-week intervals to inform them of any scheduling changes. Approximately 1 week before the examination the patients were again contacted to confirm the appointment times and to inform them of a small reimbursement for their participation. All of the patients who initially agreed to participate did, in fact, do so, and no patient was asked to be a subject for more than 2 examining sessions.

At the conclusion of the patient's first examination he was asked to complete an anonymous 7-item questionnaire before leaving the examining area. The questionnaire, which consisted of 6 structured items and 1

open-ended question, was developed by us to assess both the amount of stress experienced by the patient and his attitudes concerning his role as an examination subject. All of the 78 participants completed the questionnaire.

FINDINGS

The first item called for the patient to answer yes or no to 3 questions related to the statement, "Some people have said that patients are often asked to do things that they don't agree with or understand." Thirty-eight percent of the respondents indicated that they felt this way in general, 9% felt this way about the interview that had just been completed, and 96% stated that the purpose of the interview was explained satisfactorily.

Item 2, a multiple-choice question, sought to determine how stressful the interview was for the patient. Thirteen percent of the patients found it very stressful; 26%, moderately stressful; 5% minimally stressful; and 56%, not stressful.

The third item asked whether the patient felt that he had been treated with courtesy and respect. Ninety-six percent of the patients answered yes.

Items 4, 5, and 6 were multiple-choice questions that sought to measure the patient's feelings about his participation in the examination and his willingness to be involved in similar activities in the future. Two of the choices for each item had a positive loading and two a negative loading. Of the 234 potential responses to the 3 items, 229 choices were actually made, with only 11 (5%) being negative responses. Of these 11 responses, 6 were contributed by 2 patients on the research ward.

Item 4 asked the patient to choose the answer that best described his feelings about participating in the examinations. Ninety-six percent of the patients selected the positive choices; 30 said that it was "Worthwhile because it helped out the hospital," and 43 said that it was "An interesting and helpful experience to me personally." Three patients selected the negative choices; 1 said that it was "Something I could do without," and 2 said that it was "Tolerable because of the five dollars I was paid for the interview."

The fifth item asked whether the patient would make himself available for similar examinations in the future. Ninety-five percent of the patients selected the positive choices; 29 said that "I would make myself available as a subject whether they paid me or not," and 44 said that "I would do it again because it was important to me and the hospital." Four patients selected the negative choices; 3 chose the statement, "I would make myself available only if they paid me," and 1 the statement, "I wouldn't participate the next time."

Item 6 asked the patient to indicate how he felt about participating in activities that did not directly contribute to patient care. Ninety-five percent of the patients selected the positive choices—"They provide an interesting change in the normal routine" (N=14) and "They serve an important purpose and therefore should be encouraged" (N=58). Four patients selected the negative choices—"They don't contribute to patient care and therefore should be banned" (N=1) and "They don't mean much to me one way or the other" (N=3).

The open-ended item, number 7, invited the patient to suggest ways in which future examinations could be improved. Of the 28 responses, 12 were expressions of support for the activity (e.g., "Very good," "Keep up the good work"). Six patients commented on the beneficial nature of the examination ("Good for the upcoming psychiatrists," "Beneficial for people with problems like mine," "It shows the hospital is improving itself"). The remaining 10 comments were related to aspects of the interview. Although 2 of these were decidedly positive, the other 8 suggested that the respondents had negative feelings about the examining session. Illustrative of this group are such statements as "Make it longer," "Start the interview on time," "The doctors asked the same questions," and "The doctors should be better acquainted with the history in order to ask more helpful and logical questions."

DISCUSSION

The results of our survey indicate that although 39% of our subjects described their experience as moderately to extremely stressful, the overwhelming majority viewed their participation as a strongly positive and potentially beneficial personal experience. Almost all of them felt that they had been treated with courtesy and respect, and they indicated a willingness to participate in future examinations regardless of possible compensation. They took pride in the fact that they had been instrumental in a process that was beneficial to both their hospital and the education of the candidate.

These strongly positive responses confirm and strengthen the findings reported 7 years ago by Eveloff and McCreary (4). Despite significant differences in setting, patient population, methodology, response rate, and questionnaire format, the basic similarity in these two sets of results strongly supports the validity of these findings and suggests their applicability to other groups of patient-subjects.

In comparing the actual findings of these two studies, we found that the factors which seem to have been most responsible for the significantly higher frequency of positive responses in our sample were the loyalty of our patients to the institution and our emphasis on the preparation of the patients through continuing personal contact with a member of the staff responsible for the organization of the examination. During this preparatory process the patient was encouraged to feel that he was an important contributor to the success of the examination process. In addition, the presentation of the examination as a source of benefit to others en-

abled the patient to "use" his difficulties in an adaptive manner, thus increasing his sense of self-esteem.

Although our sample was small, confirmation of the importance of this preparatory process is suggested by the fact that most of the negative responses to the experience were reported by the patients on the research unit, who were not directly exposed to this approach. It is also interesting to note that after the interview, some of our patients spontaneously reported evaluations of the candidates' skill. Issues of confidentiality precluded an investigation of this observation, but it was our impression as well as that of some examiners that the patients' assessments were often quite accurate, and it seemed possible that the degree of stress reported by some of the patients was related to the degree of skill exhibited by the candidate.

CONCLUSIONS

If the patient is viewed as an important contributor to the success of the endeavor, his or her participation as a subject in the ABPN Part II examination can be a positive, even beneficial experience despite a significant degree of stress. Although many questions regarding the value of this examination remain unanswered, the response of most patients is perhaps best expressed in the words of the patient who concluded his questionnaire with the statement, "More examinations!"

1979 Fall Committee Meetings to Be Held in Baltimore

The 1979 APA Fall Committee Meetings will be held September 19–22, 1979, at the Baltimore Hilton Hotel in Baltimore, Maryland.

Educating Staff to Manage Threatening Paranoid Patients

BY G.A. WILLISTON DI BELLA, M.D.

The threatening paranoid patient is one of the most frightening and difficult patients to treat. The author points out the need for all levels of hospital staff to become more adept at recognizing their own feelings, which often keep them from appropriately managing these patients. He summarizes several crucial points in teaching staff to cope successfully, dividing the process into diagnosis, management of one's emotions, and practice of appropriate therapeutic techniques.

FEW PATIENTS stir up as much fear and anxiety as those who are hostile and paranoid (1, 2). The patient's threats of violence, violent acts, and terror all induce fright among all levels of hospital staff. Too often staff members have not been trained to prevent violence and maintain treatment when confronted with threatening patients (3).

The psychiatrist can take a role in changing this situation. He or she can educate the staff to deal with the hostile paranoid patient. The three-step process outlined in this paper is based on my years of experience and on a review of the literature. Although my focus is on paranoid patients, many of these recommendations can be applied to all threatening patients. To make this education maximally effective, the psychiatrist must be attuned to the times when the staff is most receptive, i.e., at times of crisis. An example of a crisis is when the staff ask permission to transfer the patient out of their care.

DIAGNOSIS

The first step in helping staff deal with the threatening patient involves enabling them to recognize this type of patient. Too often this process is neglected in multidisciplinary work.

Received Oct. 11, 1977; revised Dec. 12, 1977; accepted March 14, 1978.

Dr. Di Bella is Clinical Assistant Professor, New York University School of Medicine, and Head of Residency Training and Medical Student Education in Psychiatry, Cabrini Medical Center, New York, N.Y. Address reprint requests to him at 20 East 9th St., New York, N.Y. 10003.

The author would like to thank Mr. John Kirk and Ms. Helen Houston for their many suggestions and discussions.

The meaning of "paranoid" needs to be made clear. The APA glossary (4) defines it as oversuspiciousness. *DSM-II* lists six paranoid diagnoses. As in any syndrome, it is the combination of signs and symptoms that confirms the diagnosis of paranoid pathology. The additional feature in hostile paranoid patients is that they threaten violence or are violent.

To help staff appreciate the diagnostic features of the hostile paranoid patient, the teacher should select actual patients and review with staff specific examples of verbalization and other behavior that show how the paranoid patient thinks and feels.

I have selected from among the paranoid patients I have treated a number who exemplify the seven types of paranoid thinking described by Swanson and associates (1). Some of the examples could fall into more than one category.

Projective thinking. After knocking the ward psychiatrist to the floor one patient said, "God told me to beat him up."

Suspiciousness. To any friendly approach, a patient said something like, "Don't come off like you are my friend when I know you just want me to stay locked up in this miserable jail."

Viewing the world as a hostile place. Particularly frightening to staff, and often indicative of imminent violence, is the "paranoid stare" (I call it "devouring with the eyes"). This stare is a peculiar, penetrating, unblinking look with raised upper and lower eyelids.

Fear of loss of autonomy and control. One patient refused to get involved in activities: "Activities are for children," he said.

Feeling of self as a pivotal point of events. One day the staff gave a patient's refrigerator a much-needed cleaning. In the process, the patient's food was shifted from one shelf to another. Without really looking, this patient exploded violently, saying, "I knew they were out to get me; they took my food."

Grandiosity. At times one patient condescendingly displayed his feelings of self-importance as he expounded on the "one true way" of socialism. Sometimes he tried to show that he was a staff member rather than a patient by helping to manage other patients or doing other ward work.

Delusions. One patient hated medications. He firmly believed that they were poison. Consequently, he did everything possible to avoid receiving medication.

There are many examples of paranoid behavior available to get staff involved in an exploratory process, not only to understand the paranoid patient but also to begin exploring themselves.

0002-953X/79/03/0333/03/$00.40 © 1979 American Psychiatric Association

SELF-MANAGEMENT

The second step in learning how to deal with threatening patients is learning how to manage oneself. The therapist, for example, must become aware of, and master, his or her own feelings before he or she can manage a patient.

Staff members often react to threatening patients with fear, anxiety, anger, frustration, helplessness, guilt and hopelessness. Each staff member reacts differently, has habitual ways of dealing with dysphoric feelings, and has different physiological responses to dysphoria. The teacher can help staff members control their reactions and mental mechanisms.

The first help the teacher can provide is to reassure the staff member that strong reactions to hostile paranoid patients are normal. Second, the teacher can outline what happens to staff, perhaps by drawing a graph listing the expected emotional reactions to a hostile patient (fear and anxiety, anger, frustration and helplessness, guilt, and self-doubt) and the subsequent mental mechanisms used to cope with these reactions (denial, withdrawal, identification with the aggressor, displacement, reaction formation, submissive-seductive maneuvers, and projection).

Third, the teacher can review some specific examples of staff behavior that illustrate the mechanisms in action. This allows them to focus in on these and begin to ask themselves what emotion led to what behavior. Examples follow:

Denial. Denial was the mechanism used most often by staff. They "forgot" the patient's episodes of violence, delusions, and hallucinations. Before being beaten up by a patient, one staff member said, "He is just misunderstood; he would never hit me."

Withdrawal. Some staff members were aware that they stayed away from hostile patients because of fear. Others neglected the hostile patients and really seemed to forget that they existed. Others withdrew from certain crucial interactions, e.g., setting firm, fair limits.

Reaction formation. Some staff members took the attitude of, "I don't hate or fear you; I want to mother and rescue you." Taken too far, this reaction would only further agitate the typical paranoid patient.

Displacement of anger. Anger was usually displaced toward authority figures among the staff itself. Staff members protested limit setting and thus encouraged paranoid attitudes in the patient: "Of course, the patient is angry and violent. Who wouldn't be? All he needs is to be free!" Paranoid patients induce extreme divisiveness among hospital staff as well as in their own families.

Acting out. Punitive retaliation is not uncommon among staff members dealing with "bothersome, problematic" patients. The paranoid patient tends to push staff into such acting out. Actually, all patients tend to behave in ways that provoke responses in other people that just confirm their predetermined views of the world.•

Finally, the teacher can make sure that individual staff members do not have to deal with their dysphoria alone. He or she should repeatedly state that therapists are expected to have problems and see to it that opportunities to discuss these with supervisors and in conferences are readily available.

PRACTICAL TECHNIQUES

The final step in ensuring that staff learn to treat hostile patients appropriately is to teach them and help them practice techniques and strategies of managing the hostile paranoid patient.

The therapist must take a scrupulously frank, honest, straightforward, and structured approach to the threatening patient. He or she must not be too warm and friendly or attempt to get close quickly. Touching the patient must be curtailed. Similarly, staff members should not approach the paranoid patient suddenly and rapidly. These patients often attack in response to minimal surprises.

The paranoid patient is exquisitely sensitive to admitting deficiencies and often will not seek out help; thus, the staff will have to take the initiative in offering their resources to the patient. Issues of controlling violence must be discussed very early in therapy. The patient must be strongly encouraged to take responsibility for his or her actions, to become aware of anger mounting to a dangerous degree, and to have contingency plans prepared long in advance to handle this in an acceptable way. The patient must be told openly that in no circumstance is violence acceptable. The staff must make it very clear to the patient what will happen if he or she becomes violent, i.e., the patient's lack of control will be replaced by the staff's firm control. As a general rule, all patients fear and exaggerate unknown "punishments" for breaking rules. They will often break rules just to find out what the "penalty" is.

The patient's family should always be actively engaged in the therapeutic process. They need to learn how to avoid provoking the patient. Hostile patients are more often violent toward close relatives than toward others.

Medication is another crucial area that is usually neglected. The staff fails to consider the implications of the fact that the paranoid patient might really believe that the medication is poison. Too often the staff ask, "What should we do? The patient is on huge doses of medication but is not responding." In the majority of these cases the patient has found an ingenious way not to ingest the medication. The staff should thoroughly explore the patient's feelings about medication and help the patient work through his resentment and/or his feeling that taking medications relieves him of any responsibility for his behavior. A long-acting injectable medication, such as fluphenazine decanoate, might be considered over oral medication.

Managing imminent or actual violence has been fairly well covered in the literature (5, 6). However, a few

points bear emphasizing. The paranoid person does not just explode "out of the blue." There is almost always a period of mounting tension and turmoil and/or excessive angry brooding. Optimally, intercession should occur during this period. Staff will have to know how to restrain a patient, and they will not be able to unless someone trains them, including role playing in the training. Training films are available (7).

When an episode of violence actually occurs, it should be discussed openly and thoroughly with the patient. In addition, a staff discussion should always be held as soon as possible so that staff have the opportunity to identify their fear, ventilate, and then discuss ways of doing better. Otherwise the fright will remain or be rapidly converted and crystallized into inappropriate behavior and attitudes. Similarly, the episode must be discussed with the rest of the patients on the ward.

Staff members may wish to read other suggestions in the literature (1–3, 5–8). A general rule to judge whether appropriate therapeutic techniques are being used is the following: if the staff's behavior consistently produces appropriate patient behavior, it is correct.

Reviewing the information provided here with staff in a concerted way, along with providing specific examples of inappropriate behavior by staff, is essential in the process of enabling staff to deal with the hostile patient in a therapeutic way.

Early Review of Annual Meeting Papers

The *Journal* will continue this year its policy of early review of annual meeting papers. Final versions of papers that are ready before the Chicago meeting will be accepted for review. Do *not* submit your paper early if you anticipate substantive revisions after discussion at the meeting. Manuscripts should be submitted in triplicate, double-spaced throughout, and prepared in conformance with *Journal* style specifications, including length limitations. Papers written in "speech" format should not be submitted.

Please label the paper "Annual Meeting 1979, Final Version" and include on the title page the address and phone number of the corresponding author and the number of words, tables, and figures. The cover letter should incorporate the copyright transfer statement described in "Information for Contributors."

Since the *Journal* has first refusal rights for annual meeting papers, it is necessary to obtain the Editor's permission before submitting a paper elsewhere.

If your paper will not be ready for review before the meeting but will be in final form at that time, bring three copies to Chicago and submit them to the session Secretary (submitting copies to the Press Office *does not* satisfy this requirement). Again, papers that are not ready for review should not be given to the Secretary.

If you have questions about this or other *Journal* policies, please stop by the *American Journal of Psychiatry* staff office during the meeting, and staff members will be pleased to assist you.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

EEG Observations During Combined Lithium and Neuroleptic Treatment

BY RICHARD ABRAMS, M.D., AND MICHAEL ALAN TAYLOR, M.D.

In a recent report, Spring (1) recommended EEG monitoring for patients receiving combined lithium and neuroleptic drug therapy on the basis of EEG findings in three patients who purportedly developed encephalopathy as a result of a combination of lithium and thioridazine.

As part of a larger study, we collected EEGs on a sample of patients receiving lithium and/or neuroleptics, in order to provide data on the EEG effects of such drug treatment.

Method

The subjects included all consecutive admissions to an adult, acute-treatment university psychiatric service for 22 months ending May 1976.

Twenty-minute scalp-recorded resting EEGs were obtained in all cooperative patients, usually with sleep. The International 10–20 system and unipolar and bipolar montages were used. EEGs were read by an electroencephalographer (R.A.) who was blind to any information that could identify the patient or indicate psychotropic drug status. All records were classified as normal, borderline, or abnormal, according to the criteria of Gibbs and Gibbs (2). Borderline and abnormal records were subsequently combined for analysis.

Results

A total of 131 patients provided EEGs. Of this group, 68 were drug-free, 17 were taking lithium, 33 were taking neuroleptics, and 13 were receiving lithium and neuroleptics at the time of recording. Each of the 13 patients in the combined-treatment group was receiving haloperidol. Of the 33 neuroleptic-only patients, 30 were receiving haloperidol and 3 chlorpromazine. For purposes of calculating mean dosages of neuroleptics received, chlorpromazine was converted to haloperidol at a 10 to 1 ratio.

The mean lithium dosage for the combined therapy group was 1431 mg/day (range=900–1800 mg/day), with a mean serum lithium level of 0.94 mEq/liter (SD=0.32). The mean haloperidol dosages were 39 mg/day (range=20–60 mg/day) for the combined-treatment group and 38 mg/day for the neuroleptic-only group.

There was no significant difference in the distribution of EEG abnormalities for the four groups or for the 3 drug treatment groups considered alone (see table 1).

Comparisons of the groups separately revealed no differences in EEG abnormalities between the lithium-only and the combined-treatment groups or between the neuroleptic-only and the combined-treatment groups. Finally, there were no significant correlations between serum lithium level and presence of EEG abnormalities for patients in the lithium-only or combined-treatment groups or for the entire lithium sample.

Conclusions

The combination of lithium and haloperidol produced no more EEG abnormalities than either drug given alone or than no drug at all. This finding, which is consistent with our previous report of a lack of clinical neurotoxicity for combined therapy (3), fails to support the need for EEG monitoring of such treatment. It is possible that Spring's patients (1) may have demonstrated anticholinergic delirious states secondary to thioridazine, the most potent anticholinergic

neuroleptic available. This is suggested by his description of the first and fourth patients, who showed no abnormalities when lithium was combined with other neuroleptics but developed a transient encephalopathy when lithium was combined with thioridazine. The case of the first patient described by Spring was particularly unfortunate; she had done well on combined lithium and haloperidol for a year and was changed to the more toxic lithium/thioridazine combination because of apprehension engendered by the report of Cohen and Cohen (4).

Postcardiotomy Delirium and Cardiac Output

BY STANLEY S. HELLER, M.D., DONALD S. KORNFELD, M.D., KENNETH A. FRANK, PH.D., AND PAUL F. HOAR, M.D.

Thirteen years following its initial description, delirium after open-heart surgery continues to occur. The phenomenon consists of a lucid interval followed by illusions and/or disorientation and at times progresses to hallucinations and/or delusions. A number of factors have been found to correlate with this delirium, and a multicausal etiology has been postulated. The existence of the lucid interval led to the hypothesis that the delirium was a reaction to the impact of the open-heart surgery recovery room (OHRR) experience in patients made vulnerable by the physical effects of cardiac disease and surgery (1–3).

An association between postcardiotomy delirium and postoperative cardiac index (cardiac output/surface area) has also been shown. In 1966, Blachly and Kloster (4) studied 37 cardiotomy patients who had undergone valve replacement. Cardiac output was measured pre- and postoperatively by a radioisotope dilution technique with ^{131}I-labeled albumin. Charts were evaluated blindly as to the presence of either organic brain syndrome or hallucinosis. The authors found that the great majority (81%) of patients in their series had some evidence of organic brain syndrome. It was marked in 22%, moderate in 32%, and mild in 27%. A marked brain syndrome was generally associated with cardiac index below 2.5 liters per minute per meter squared during the early postoperative period. Conversely, higher outputs were associated with less cerebral dysfunction. Forty-six percent of the patients experienced hallucinosis, some without evidence of brain syndrome. The hallucinosis tended to occur later and was suggestively related to periods of rising cardiac output.

The improvements in cardiac surgery and cardiopulmonary bypass techniques and the development of a thermodilution method (5, 6) that more accurately measures actual cardiac output called for a new study of the relationship between cardiac output and delirium.

Method

We studied 48 patients who had a single valve replacement at Columbia-Presbyterian Medical Center between July and November 1977. Patients were equally divided between aortic and mitral valve cases receiving glutaraldehyde-treated porcine heterografts. A triple-lumen flow-directed thermodilution catheter was introduced and the average cardiac output was determined via the thermodilution principle by using a

Delirious	18	2.70	2.35	2.11	2.29	2.29	2.26	−16.3	

cardiac output computer. During cardiopulmonary bypass, the adult Bentley oxygenator and cardiotomy reservoir were used. A nonhemic prime and hypothermia to 28° were employed. The cardiac index was sequentially measured preoperatively, at the time the chest was closed, on admission to the recovery room, and on the first two postoperative days. A mean postoperative cardiac index score was calculated. Informed consent was obtained from the patients after the procedure had been fully explained.

Delirium was diagnosed by blind chart review (3). Patients were judged to have a delirium if they experienced a lucid interval and then doctors' or nurses' notes in the postoperative week described either illusions, inability to distinguish dreams from reality, disorientation, hallucinations, or delusions. As a result of our earlier work (1–3), inquiry into these issues is done routinely in the OHRR. Student's paired and unpaired t tests were used to determine statistical significance.

Sample. The aortic valve replacement group (18 men, 6 women) ranged in age from 28 to 75 years, with a mean age of 60.8 years. Aortic stenosis was the main problem in 21 patients, insufficiency in 3. Four patients had concomitant coronary bypass procedures. Mitral patients (17 women, 7 men) were younger, with a mean age of 54.2 years and a range of 30–76 years. Mitral stenosis was the main problem in 14 patients, insufficiency in 10.

Results

Delirium was seen in 38% of our total sample. Eleven of the aortic patients (46%) developed delirium. Mean ages were 56.6 years for clear aortic patients and 65.8 for delirious patients. Bypass times were comparable (115.1 minutes for clear patients and 118.3 for delirious patients). Differences in cardiac index between the clear and delirious patients are shown in table 1. There was an overall decrease in the cardiac index for the whole aortic group, but the delirious group had a significantly greater decrease than the clear patients ($p<.02$). The delirious patients also showed a significant decline in cardiac index compared to their preoperative values ($p<.003$), while the clear patients showed only a slight change.

Among the mitral patients, the incidence of delirium was less (29%). Mean ages were 53.5 years for clear patients and 55.9 years for delirious patients. Unlike the aortic patients, cardiopulmonary bypass times differed between clear and delirious mitral patients (94.1 versus 121.7 minutes). There was a significant increase in cardiac index postoperatively for the clear mitral patients ($p<.05$), while delirious mitral patients had a statistically suggestive ($p<.07$) decrease. Mitral patients with delirium were the only group whose cardiac indices did not increase in the first 2 postoperative days. When the aortic and mitral valve groups were combined and the change in cardiac index was studied for the entire sample, a significant difference was found: clear patients' cardiac indices increased, whereas those of delirious patients decreased ($p<.005$).

Discussion

An association between postcardiotomy delirium and a low postoperative cardiac index has been confirmed in this preliminary study. This relationship is probably due to an associated impairment of cerebral perfusion. Our patients had a lower incidence of cerebral dysfunction than that reported by Blachly and Kloster (38% versus 81%), which is consistent with other studies showing a decrease in incidence since the earliest reports (2, 7).

Aortic valve patients with a clear sensorium showed a relatively unchanged cardiac index postoperatively, while delirious aortic patients showed a decrease of almost one-fifth. Clear mitral valve patients had increased cardiac output, while delirious mitral patients showed a slight decrease.

Although mitral valve patients had lower cardiac indices (8), the incidence of delirium was higher for aortic valve patients. It may be that aortic valve patients, who are accustomed to better cardiac function, were less able to tolerate low postoperative cardiac outputs. Mitral patients, on the other hand, may be adapted to low cardiac output associated with cardiac failure. Aortic valve patients were also older than mitral valve patients, and age could have also contributed to the higher delirium incidence.

Blachly and Kloster (4) noted that a rapidly rising output was associated with hallucinosis, although they did not report statistical confirmation. We were unable

to study cardiac output beyond the second postoperative day, so we can make only limited comments on this issue. However, all patients except the delirious mitral group had increases in cardiac output during the first 2 postoperative days. Additional measurements over the postoperative week would be necessary to confirm Blachly and Kloster's observation. It is also possible that the later occurrence of hallucinosis in their series was associated with patients' continued stay in the OHRR, rather than the continued rise in cardiac index.

It has been postulated that in the stressful OHRR environment the patient with an impaired brain is most delirium-prone (1–3). Age, time on the cardiopulmonary bypass pump, intraoperative hypotension, pre- and postoperative severity of illness, sleep deprivation, sensory monotony, and the personality traits of dominance, confidence, and composure have been associated with delirium (1–3, 7, 9, 10). Cardiac index is therefore another associated postoperative physical variable.

Clinical Utility of Tricyclic Antidepressant Blood Levels: A Case Report

BY PAUL S. APPELBAUM, M.D., RUSSELL G. VASILE, M.D., PAUL J. ORSULAK, PH.D., AND JOSEPH J. SCHILDKRAUT, M.D.

The recent availability of procedures for measuring plasma levels of tricyclic antidepressants promises to increase the precision of pharmacologic treatment of depressions (1). An unusual example is provided in the following case report.

Received Oct. 6, 1978; accepted Nov. 22, 1978.

Dr. Appelbaum is Clinical Fellow in Psychiatry, Dr. Vasile is Instructor in Psychiatry, Dr. Orsulak is Assistant Professor of Psychiatry, and Dr. Schildkraut is Professor of Psychiatry, Harvard Medical School, Boston, Mass. Dr. Schildkraut is also Director and Dr. Orsulak is Associate Director, Neuropsychopharmacology Laboratory, Massachusetts Mental Health Center, where Dr. Appelbaum is Resident in Psychiatry and Dr. Vasile is Staff Psychiatrist. Case Report

Ms. A, a 68-year-old woman with a history of recurrent unipolar depressions since her teens, has had 13 hospitalizations at several institutions during the last 12 years. During that period she received 4 separate courses of ECT, totaling 100 treatments, with modest response. Phenothiazines in large doses had limited impact on her illness. Lithium therapy was attempted twice but had to be withdrawn because of ataxia and tremulousness.

Tricyclic antidepressant therapy was first initiated in 1969, and Ms. A exhibited some clinical response to a combination of amitriptyline (75 mg/day) and perphenazine (6 mg/day). She showed complete recovery when the amitriptyline was increased to 200 mg/day. However, from 1970 to 1975 she had many recurrent episodes of depression, some of which were treated with amitriptyline in doses of 75–125 mg/day. The maximum clinical benefit during this period occurred when the patient received perphenazine (12 mg/day) in addition to amitriptyline (125 mg/day). From 1972 to 1975, tricyclic antidepressants were discontinued and Ms. A received phenothiazines and ECT.

In 1975 Ms. A was admitted to the Massachusetts Mental Health Center for the first time, and treatment with tricyclic

0002-953X/79/03/0339/03/$00.40 © 1979 American Psychiatric Association

antidepressants was reinstated. She responded to a very low dose of amitriptyline (50 mg/day) without concomitant use of phenothiazines. In June 1976, the patient stopped taking the amitriptyline and experienced a recurrence of depression. Upon rehospitalization, she was placed on amitriptyline (100 mg/day) without phenothiazines. She began to improve but soon became disoriented, with severe memory deficit, incontinence, somnolence, and, ultimately, coma. Four days after amitriptyline had been discontinued she had a pulse of 160, respiratory rate of 22/minute, temperature of 101° F, and no focal neurologic signs. An extensive neurologic work-up, including lumbar puncture, brain scan, and EEG, revealed no cause for her symptoms. Physostigmine was not administered. Eight days after the discontinuation of amitriptyline, the syndrome had resolved. Her depression persisted despite treatment with acetophenazine (60 mg/day) but responded to the addition of imipramine (50 mg/day).

In September 1977 Ms. A again stopped taking her medications, became depressed, and was readmitted to the Massachusetts Mental Health Center. She improved on imipramine (75 mg/day) and acetophenazine (40 mg/day), but when the imipramine dose was increased to 100 mg/day she experienced intermittent relapses that responded to dosage decreases.

She had been successfully maintained after discharge on imipramine (75 mg/day) until a sudden decompensation led to her hospitalization on Feb. 21, 1978. As in previous depressive episodes, she was agitated and diaphoretic, she responded to questions with "no" or "I don't want to" and she walked with what appeared to be an antalgic gait, which in the past had resolved as the depression cleared. She would not cooperate with formal mental status testing. Physical examination, liver function tests, and the remainder of her routine clinical chemistry tests were all within normal limits. Her weight was approximately 49 kg.

At the time of this admission the dose of imipramine was increased to 100 mg/day and acetophenazine, 20 mg/day, was added. The patient's failure to respond to this regimen after 2 weeks prompted her physician on March 7 to obtain plasma levels of tricyclic antidepressants, which were determined by gas-liquid chromatography using a nitrogen detector (2). He expected to find low levels and was surprised to discover that her total plasma tricyclic antidepressant level was 805 ng/ml (imipramine=193, desipramine=612), which is far above the usual therapeutic range of 180–250 ng/ml (3, 4). Imipramine was stopped on March 8, but acetophenazine (20 mg/day) was continued. A repeat sample drawn on March 9 revealed a total plasma tricyclic level of 696 ng/ml (imipramine=174, desipramine=522). It is noteworthy that physical examination at this point failed to reveal evidence of atropinic toxicity: pulse was 120, skin was diaphoretic, pupils were reactive to light and were not dilated, and there was no facial flushing, dry mouth, or difficulty with urination. On March 12, 3 days after imipramine was discontinued, Ms. A became less agitated, cooperated with nursing staff for the first time, and began to converse socially in an appropriate fashion and to play the piano. Mental status examination revealed a clear sensorium, marked improvement in depressive mood, and no evidence of psychosis. The next day, treatment with imipramine was resumed at a dose of 25 mg/day. On March 20, the patient was stable and recompensated, and her total plasma tricyclic level was 252 ng/ml (imipramine=51, desipramine=201). At this point Ms. A was discharged to a nursing home.

Ms. A was readmitted to the hospital on March 31 because her depressive syndrome had reemerged. The total plasma tricyclic level had fallen to 143 ng/ml (imipramine=23, desipramine=120), which is below the therapeutic range. Poor medication compliance may have caused this decrease. On April 1, the dose of imipramine was increased to 25 mg and 50 mg on alternate days. On April 20, she remained unimproved and acetophenazine was increased from 20 mg/day to 40 mg/day. One week later, the patient recompensated, becoming pleasant and talkative. On May 2, the plasma tricyclic level was 307 ng/ml (imipramine=85, desipramine=222). Ms. A was discharged on May 12 and 3 months later remained in remission while continuing to receive acetophenazine, 40 mg/day, and imipramine, 25 mg/day alternating with 50 mg/day.

Discussion

During the patient's most recent admission, accepted clinical practice would have called for an increase in the dosage of imipramine in the face of a failure to respond to a modest dose (100 mg/day). However, when plasma tricyclic levels were obtained on March 7, it became clear that they were approaching the toxic range and that a decrease in dosage was indicated. In the absence of the determination of plasma tricyclic antidepressant levels, neither clinical psychiatric evaluation nor physical examination would have led to the proper psychopharmacologic response.

The exceptionally high plasma levels that were found in spite of the relatively low daily doses shed new light on the patient's toxic episode in 1976 and suggest the possibility of a similar etiology then. Of note is an apparent decrease in the patient's tolerance for tricyclic antidepressants as she aged, a finding that has been reported elsewhere and that should emphasize the need for caution in prescribing for geriatric patients (5). An additional factor in the attainment of toxic levels in this case may have been the concomitant administration of acetophenazine. Phenothiazines have been reported to inhibit the metabolism of tricyclic antidepressants, especially of demethylated derivatives such as desipramine, thereby elevating effective blood levels despite stable oral doses (6, 7). In this regard it is of interest that every determination in the present case showed much higher plasma levels of desipramine than imipramine. Finally, this patient's failure to respond at high plasma levels and subsequent improvement at lower doses raises the possibility that, at least for some patients, there may be a therapeutic window for imipramine or desipramine similar to that previously reported for nortriptyline (1).

Rapid-Cycling Affective Disorder During Imipramine Treatment: A Case Report

BY SAMUEL G. SIRIS, M.D., HARVEY R. CHERTOFF, M.D., AND JAMES M. PEREL, PH.D.

Rapid-cycling mood disorders have been recognized as rare but dramatic and potentially informative manifestations of affective disease. A review of the world literature in 1965 by Bunney and Hartmann (1) revealed clinical descriptions of 10 48-hour cyclers, and more recently several other cases of rapidly cycling bipolar disease have been studied biologically (2-4). None of these reports, however, has linked a rapidly cycling course with the use of an antidepressant agent. The present communication details a rapidly fluctuating affective disorder which occurred after treatment with imipramine had been initiated in a woman with a postpartum depression.

Case Report

Ms. A, a 30-year-old married mother of two, had no notable psychiatric difficulties until age 27. At that time, several weeks after the birth of her first child, Ms. A experienced conflict because her son seemed to do better on formula than on breast milk. This was soon superseded by persistent feelings of depression, irritability, anxiety, worthlessness, and loss of sleep. After several weeks of suffering, she sought psychiatric help and was treated first with amitriptyline, 75 mg/day, and then with desipramine, 75 mg/day. Although her sleep improved, her dysphoric mood, lack of interest, and diminished ability to function persisted for 4 months, at which time they gradually abated and she felt like her "normal self" again. Medication was then discontinued. She had no history of episodes of acceleration, euphoria, or irritability.

She remained well until the birth of her daughter 3 years later. When the child was 3 months old, Ms. A again experienced a similar conflict over breast feeding, coupled with apprehension about her parents retiring and moving to another state. She became depressed once again, with prominent tearfulness, doubting, preoccupations about her lack of capacity, feelings of guilt, decreased energy, decreased ability to concentrate, poor appetite, and middle and late insomnia. Her symptoms were worse in the morning than in the evening. After 3 weeks of steady depression, she consulted a psychiatrist once again and started taking imipramine. After 12 days of imipramine treatment at a dosage of 100/mg day, she had a 48-hour period of cheerfulness and increased energy, which made her think temporarily she was "back to her old self." This episode ended abruptly, however, and she returned to her depressed state for the next 2 weeks. On the 28th day, this time on a dosage of 175 mg/day of imipramine, she again came out of her depressed state for approximately 48 hours. During that interval she had a night in which she slept only 2 hours but woke feeling fully rested. She described feeling "better than my usual self" and decided to join a bowling league but did nothing else unusual. This signaled the start of a 2-month period during which she emerged from and then relapsed into a depressed state seven separate times. During this period her imipramine dose was raised gradually to 300 mg/day (4.4 mg/kg, with a steady-state plasma concentration of 180 ng/ml) without alteration of her cyclic mood pattern. Her nondepressed intervals ranged from 2 to 6 days and her depressed episodes from 3 to 7 days. The transitions between these states seemed unrelated to external events and occurred abruptly over a few hours, during which time Ms. A felt herself either "slipping" or "snapping out of it." When she was not depressed, Ms. A was at times euthymic and at other times mildly hypomanic, with more than her normal level of energy and enthusiasm, and she occasionally required as few as 2 hours of sleep. Her judgment remained sound, however, and she was neither giddy nor irritable. She was unmistakably different when depressed: hopeless, devoid of pleasure, self-critical, nonfunctional, and thoroughly miserable.

On the 85th day of imipramine treatment, when Ms. A was "due" to come out of one of her depressed intervals, oral lithium carbonate was begun. The dose was rapidly stabilized to give a serum level of 0.7-0.8 mEq/liter. On day 86 of imipramine treatment, Ms. A switched back to her normal euthymic state and remained there. Imipramine was continued at 300 mg/day until day 122, when the dosage began to be tapered off. Imipramine was completely discontinued on day 186. Lithium treatment was continued for an additional 12 months, then discontinued, and the patient has remained well.

Ms. A's family history is remarkable in that her mother suffered two clinical depressions. One, which occurred during the first trimester of an unplanned pregnancy, resolved spontaneously. The second depression, at age 65, was treated with imipramine for 5 months before responding

promptly to ECT. Retrospective analysis of the mother's case history revealed two abrupt and otherwise unexplained 48-hour episodes of feeling active, confident, and enthusiastic while on imipramine. These episodes disappeared as suddenly as they had started.

Discussion

Ms. A had a postpartum depression that was phenotypically unremarkable. She met the Research Diagnostic Criteria (5) for a simple primary endogenous recurrent major unipolar depression. For 3 weeks her course had been well established. However, after starting imipramine, Ms. A underwent 15 major mood changes between depression and either euthymia or hypomania over a 10-week period. To our knowledge, such a cyclic response to imipramine in an otherwise unipolar depressed patient has not been described previously, although clear switches into persistent mania in response to imipramine have been well-documented (6, 7). It is also known that more manic attacks occur in bipolar patients being treated prophylactically with imipramine than in those being treated with lithium or placebo (6), and preliminary evidence suggests that the cycle time of some bipolar patients may be shortened by tricyclic antidepressants (8). Imipramine, of course, interacts with biogenic amine mechanisms which have been implicated in the manic-depressive "switch" process (7, 9), so that a causal relationship linking imipramine administration and the clinical syndrome exhibited by Ms. A is not implausible.

Dunner and associates (10) examined the case records of 390 bipolar patients and found that 13% were "rapid-cyclers" according to their criterion of 4 or more affective episodes per year. As a group these patients were observed to benefit less from lithium than other bipolar patients. However, this represented a group of patients who were known to be bipolar before treatment and were not being treated with a tricyclic antidepressant. The subset of affectively ill patients whose only manifestations of hypomanic or manic characteristics occur while they are under treatment with tricyclic antidepressants has not yet been separated out for study. Ms. A's favorable response to lithium, as a single case, is of course inconclusive. Nevertheless, our experience would encourage us to identify similar cases and attempt a lithium trial.

Effects of Training Schedule and Biofeedback on Speech Dysfluency

BY THEODORE WEISS, M.D., LINDA F. CARSON, M.D., AND JOHN PAUL BRADY, M.D.

Masseter muscle electromyographic (EMG) biofeedback reportedly improves speech fluency in stutterers (1). We examined the efficacy of this method and the effects of training session frequency in an older patient with speech dysfluency.

Received Nov. 13, 1978; accepted Dec. 8, 1978.

Dr. Weiss is Assistant Professor and Dr. Brady is Professor and Chairman, Department of Psychiatry, University of Pennsylvania, Philadelphia, Pa. 19104. Dr. Carson is an intern at Sinai Hospital, Baltimore, Md.

This work was supported by Alcohol, Drug Abuse, and Mental Health Administration Research Scientist Development Award MH-70906 to Dr. Weiss from the National Institute of Mental Health, and by National Institutes of Health grant RR-00040 from the Division of Research Services.

Case Report

The patient was a 64-year-old woman with mild congenita choreoathetoid encephalopathy (cerebral palsy). The cerebral palsy had not impaired her functioning, but at age 62 her speech had worsened, and her jaws started clamping shu when she spoke. She had to compress her cheeks inwarc with both hands to facilitate speech flow. Inpatient evaluation revealed no clear reason for her deterioration, and several medications (haloperidol, perphenazine, amantadine

[a]There were 10 sessions in each training phase.

diazepam, and doxepin) were administered without benefit. She was taking doxepin, 75 mg/day, for mild depression at the beginning of the study. Because her speech problem involved masseter muscle contraction, we trained her with EMG biofeedback from this area. After 20 informal training sessions, at varying intervals, we initiated the present study to examine our impression that improved speech occurred with more frequent biofeedback.

Method

EMG activity (100–1,000 Hz) from the right or left (in alternate sessions) masseter muscle was recorded with surface electrodes (silver/silver chloride) using a commercially available biofeedback device. The machine's threshold criterion was set empirically so that the patient turned on a green or yellow light when she relaxed her masseter muscle and a red light when she tensed it. She practiced this several times during the 1-hour training session. The rest of the time she spoke with a technician and was drilled in pronouncing problematic words or syllables while attempting to keep the yellow or green lights lit.

Performance was assessed by a 10-minute recording during which the same experimenter had the patient talk about a subject that interested her. Five minutes of her speech was analyzed for numbers of words and dysfluencies, defined as clearly discernible instances of words or syllables the patient had difficulty emitting.

The training sequence was as follows: 1) 10 twice-daily biofeedback sessions over 5 days, 2) 10 weekly biofeedback sessions, 3) 10 biweekly biofeedback sessions, 4) 10 weekly biofeedback sessions, and 5) 10 weekly sessions without biofeedback. In no-biofeedback sessions, after the initial recording, the patient and technician talked for 50 minutes, with no biofeedback or drill on problematic words and syllables. The tape recording was done at the beginning of every session, except during the daily biofeedback phase, when it was done only before sessions 1 (baseline, see table 1), 5, and 9. Between biofeedback sessions the patient was instructed to practice relaxing and clenching her jaw several times daily at home and to imagine the green or yellow lights when she had difficulty speaking. For the no-biofeedback sessions she was given no instructions about home practice. She gave informed consent to participate in the study.

Results

During daily biofeedback training, the patient's speech fluency improved markedly. Dysfluencies/100 words fell from 26.5 before training to 3.8 at the beginning of session 9. Speech data generally were best during this period. In the following weekly biofeedback phase speech remained good, but when biofeedback was decreased to every 2 weeks, her speech worsened. Her performance during biweekly training was worse than any other period. Of 8 sessions, 4 (numbers 2, 3, 4, and 9) showed dysfluency rates over 18.0, a high level not seen in any other sessions (except the prestudy baseline). During this biweekly biofeedback phase doxepin was discontinued after session 4 because the patient no longer seemed depressed. Speech fluency worsened dramatically in the next 2 sessions (5 and 6), with data in almost every category by far the worst seen (e.g., dysfluency rates of 53.3 and 43.9). We felt these sessions reflected aftereffects of the drug's discontinuation and dropped them from the data analysis. (These data would have strengthened our argument regarding the effect of session frequency.)

In the subsequent weekly biofeedback phase speech again improved. To assess the importance of biofeedback, we then gave 10 weekly sessions without biofeedback as described above. Speech performance was quite similar to that in the weekly biofeedback training phases.

Discussion

Weekly training sessions were more beneficial than less frequent ones for this dysfluent patient. However, we found no evidence that EMG biofeedback from masseter muscles was necessary for this improvement. Masseter biofeedback improved fluency in stutterers when the feedback-on and feedback-off conditions followed one another within a few minutes (1). Our data on a related but different issue—the persistence of benefit from masseter biofeedback during a 1-week period between training sessions—indicate that weekly practice speaking with a technician was as therapeutic as weekly biofeedback.

We cannot exclude the possibility that improved speech during the no-biofeedback phase reflected persistence of an over-learned response from many prior

biofeedback sessions. However, the patient's worsening in speech during biweekly biofeedback followed 40 prior biofeedback sessions, whereas persistently good performance in the weekly no-biofeedback phase followed 60 prior biofeedback sessions. It seems unlikely that the 20 biofeedback sessions between the first weekly biofeedback phase and the final weekly no-biofeedback phase—during a number of which the patient was quite dysfluent—were critical in her acquiring persistently improved speech.

Elder and Eustis (2) found that daily blood pressure biofeedback was more effective in lowering hypertensives' pressures than a similar number of biofeedback training sessions spread over several months. However, our data in the no-biofeedback phase suggest that an appropriate control procedure in their study—relaxation training, rapping, sitting quietly—carried out with the same frequency as blood pressure biofeedback might have been as effective in lowering patients' pressures.

The issue of nonspecific or placebo factors in biofeedback training (3) is relevant. An opportunity to speak with a familiar person was beneficial to our dysfluent patient's speech. Biofeedback was merely the mechanism by which this interaction occurred rather than an important therapeutic ingredient.

Unconscious Communication Between Father and Son

BY JESSE O. CAVENAR, JR., M.D., AND NANCY T. BUTTS, M.D.

The influence of parents and their neuroses on the developing child has long been recognized. The importance of the neurotic conflicts of the parents in the psychoanalysis or psychotherapy of the child has been appreciated since at least 1909, when Freud capitalized on his patient's relationship with his father in "The Analysis of a Phobia in a Five-year-old Boy" (1). Freud conducted the entire treatment of the boy through the father.

The importance of unconscious conflicts in the parents as a cause of conflicts in the child gained more acceptance as more experience was gathered in child psychoanalysis. By 1935, Burlingham (2) stated that "the power of unconscious forces is especially marked in its interplay between parent and child. It is so subtle and uncanny that it seems at times to approach the supernatural."

Johnson and Szurek (3) suggested that unconscious communication between the child and the parents, particularly the mother, was instrumental in the development of antisocial personality disorders. It was believed that the parent or parents unconsciously derived pleasure from the child's antisocial acts and subtly encouraged them. At the same time, the parents could discharge their unconscious hostility, sadism, and destructiveness toward the child.

Child psychoanalysts observe the intensity of unconscious parental forces when they undertake simultaneous analysis of both parent and child. Such simultaneous analysis is occasionally necessary when a parent and child are locked in a severe neurotic pattern. There are several case reports in the literature that describe the simultaneous psychoanalysis of mother and child (4, 5); we are aware of only one article (6) on the simultaneous psychoanalysis of a father and son. None of these case reports refers to specific dreams of either parent or child during the treatment.

The purpose of this paper is 1) to report a case in which unconscious communication between father and son resulted in both having dreams that used the same symbols and 2) to demonstrate the degree to which the father's conflicts influenced his son.

Case Report

The father, Mr. A, is a 38-year-old professional man who had sought psychoanalysis 10 years earlier because of anxiety, self-defeating behavior, and a fear of success. An obsessive-compulsive personality structure had led to a psychoanalysis of 6 years' duration. There was excellent resolution of his anxiety and other symptoms.

The psychoanalysis had terminated 4 years previously.

Mr. A had continued self-analysis primarily through interpreting his dreams. He had been very successful in his chosen field and had had many advancements and promotions since the analysis ended.

As a result of several significant object losses, Mr. A regressed and became clinically depressed, with weight loss, sadness, and early morning awakening. He consulted his previous analyst for assistance in understanding the depression. Anxiety dreams indicating superego tension were frequent. He described one typical dream as follows: "A snake was charging at me. I had a sling-type weed cutter in my hands, and tried to cut the snake in half. I couldn't get the weed cutter to land solidly, and kept missing the snake. The snake would crawl past, then charge from another direction." He awakened from the dream and discussed it with his wife early the following morning.

That evening, the son, who was 7 years and 10 months old, came to Mr. A to discuss his own dream of the previous night. He reported, "A snake was chasing me, and I couldn't get away from it. Every time I thought I was safe, the snake would chase me more." The son had no knowledge that his father had had a similar dream the same night.

Four nights later, Mr. A had the following dream: "A tornado was approaching; I could see the funnel. I was very anxious and hurried about telling various people that a tornado was imminent. The people wouldn't heed my warning, and continued their routine activity. I shouted, 'Believe me, this is serious.' In desperation, I grabbed a child under each arm and ran." The father awoke with anxiety and again discussed his dream with his wife early that morning.

That evening, his son came to talk to Mr. A about his own dream of the previous night, which he described as follows: "A tornado was coming after me. I was scared at first; I got sucked up in the funnel, like Dorothy in *The Wizard of Oz*. I was thrown around by the tornado, but it was fun. After a while, the tornado let me back down to the ground; I wasn't hurt." Again, the son had no knowledge that his father had had a dream using the same symbols on the same night. The son had never seen a tornado except on television and had only seen snakes in a zoo. He had no reason based in his own experience to associate either with anxiety.

Mr. A was seen for 8 hours in face-to-face psychotherapy and rapidly understood the dynamics of his depression. The depression cleared, and the anxiety dreams stopped. The son's dreams apparently also stopped; he has not mentioned a dream to his parents in many months. Obviously the atmosphere in the home is such that the son feels free to discuss dreams which are of concern to him, so we assume that he has not had further troublesome dreams.

It is important to note that Mr. A's recollection of his dreams was not retrospective falsification; he had discussed his dreams with his wife before his son reported his own dreams. We are also certain that Ms. A did not tell him of the father's dreams. She was positive that she had not told her son about them. Ms. A had also completed a successful psychoanalysis and found the similarity in dreams fascinating.

Comment

In the multiple case reports of simultaneous parent-child psychoanalysis, there are to our knowledge none that include reported dreams in which parent and child used the same dream symbols. The choice of dream symbols is poorly understood, but if parent and child employ the same symbols, simultaneous psychoanalysis should demonstrate this tendency.

Altman (7, p. 18) noted, "Each dreamer employs a preferred set of symbols chosen from the vast number available to him and uses them with considerable regularity and consistency so that they become a sort of mental fingerprint." He further stated, "A recurrent use of the same symbol must have a special significance but, to date, in not a single instance have I been able to trace any to its source in the patient's personal experience. Why does anybody use a particular symbol with such consistency that one could call it a mannerism?"

Certainly we cannot answer this question on the basis of one case report, but our work tends to suggest that persons within the same biological lines may employ the same symbols. This should be further investigated in parent-child simultaneous psychoanalysis or psychotherapy or in the therapy of twins or siblings when dreams are a focus of the treatment.

Central Nervous System Toxicity of Cimetidine: A Case of Depression

BY JAMES W. JEFFERSON, M.D.

In a relatively brief period of time, the competitive histamine H_2 receptor antagonist cimetidine has become a drug widely used to decrease gastric acid secretion (1, 2). The Food and Drug Administration has approved its use for the short-term treatment of duodenal ulcer and the treatment of pathological hypersecretory syndromes (Zollinger-Ellison syndrome, systemic mastocytosis, multiple endocrine adenomas). Other uses which require further experimental confirmation include benign gastric ulcer, gastroesophageal reflux disease, acute gastric hemorrhage, pancreatic insufficiency, and the maintenance treatment of duodenal ulcer.

The drug is generally well tolerated, but there have been a growing number of reports of neuropsychiatric toxicity associated with its use (3–10). Included in these reports are manifestations such as lethargy, coma, restlessness, agitation, disorientation, confusion, delirium, unsteadiness, slurred speech, visual impairment, and incontinence. The following case adds depression to the list of neuropsychiatric complications.

Case Report

An 81-year-old man was referred from a retirement home to the medical service of our hospital for evaluation and treatment of depression and possible recurrent peptic ulcer. Over a period of several months he had become "disgusted with life," complaining of difficulty concentrating, especially when reading and playing cards, loss of interest, a decreased ability to enjoy himself, lack of energy, difficulty falling asleep, bizarre nightmares, anorexia, and weight loss. He had no previous history of psychiatric difficulties.

Two years earlier he had developed gastric outlet obstruction secondary to peptic ulcer disease, which was treated surgically. For 5–6 weeks before the current hospitalization he complained of epigastric pains and vomiting after meals, which raised the possibility of recurrent ulceration and obstruction. He had been receiving cimetidine, 300 mg. q.i.d., for a number of months.

Psychiatric evaluation was obtained shortly after admission, and the consultant felt that the cimetidine could be responsible for the patient's symptoms and recommended its discontinuation. At follow-up 8 days later, however, the symptoms were unchanged and he was continuing to receive the drug. When it was finally stopped, the patient improved rapidly and in 2 days was more optimistic, had lost his fatalistic outlook, was sleeping and eating better, and was reading magazines and actively looking for a cribbage partner. His gastrointestinal symptoms completely resolved and at discharge he was cheerful and looked forward to resuming his prior activities.

Discussion

It appears that cimetidine can cause CNS side effects, although they are uncommon. Usually these reactions take the form of a reversible organic brain syndrome, although, as the present case illustrates, a drug-induced depressive syndrome is also possible.

Neuropsychiatric complications appear more likely to occur in the presence of 1) advanced age, 2) impaired renal function (up to 70% of an oral dose of cimetidine is excreted unchanged by the kidneys), 3) associated serious medical problems, and 4) a dosage higher than that recommended. The absence of predisposing factors does not, however, exclude the possibility of cimetidine-induced CNS effects.

With the increasing use of cimetidine in a variety of clinical settings, there may well be a steady increase in the number of neuropsychiatric complications. Prompt recognition of the apparent causative role of the drug in such situations is essential because the syndrome is readily reversible upon drug discontinuation, and if it is unrecognized, the patient will be subjected to needless suffering, increased risk of morbidity, unnecessary diagnostic procedures, and inappropriate and often dangerous treatment.

The association of CNS toxicity with the use of a histamine H_2 receptor antagonist should also stimulate further interest in the role of histamine in the CNS.

Autocastration in Transsexualism

BY MICHAEL A. HABERMAN, M.D., AND RICHARD P. MICHAEL, M.D., PH.D.

Forty-four cases of autocastration (removal of the testes rather than mutilation or amputation of the penis) have been reported in the English language literature since 1900 (1-3). In 1951, Hemphill (4) wrote about the personality traits of patients who castrate themselves, including an abnormal attitude toward the genitals, a tendency to regard the genitals as exercising influence over the whole organism, an abnormal integration of the body image that permits mutilation, a sense of intactness and relief thereafter, and a strong, conscious motivation. Hemphill contrasted genital self-mutilation with other self-inflicted injuries by pointing out that this act gives both satisfaction and relief and is not regretted by the individual.

Before the 1954 report by Esman (5), all published cases were of psychotic individuals with organized delusions. Esman described a 44-year-old nonpsychotic schizoid man who was secretly a transvestite and who impulsively castrated himself while intoxicated. The patient's complacent attitude toward "so catastrophic an occurrence" suggested that the act might have in some way gratified an unconscious wish and solved an unconscious conflict. The patient had subsequent admissions for depression and alcoholism, but 5 months later he seemed improved and was not heard from further. Cleveland (6) reported three cases of autocastration in men who were not considered overtly psychotic and who also reacted with bland acceptance. In 1971, Lowy and Kolivakis (2) described the first recorded case in which a transsexual man castrated himself. This man dated his desire to be a girl from age 6 and had started nonfetishistic cross-dressing before puberty. He claimed his sexual organs had always disgusted him and he had desired sex change surgery since adolescence. He castrated himself at age 35: the procedure was "skillfully performed," and he flushed the testes down the toilet to ensure that they could not be reattached. He seemed happier after castration and "relentlessly and successfully continued to establish his identity as a woman." The authors described him as "probably schizophrenic" for reasons that are not entirely clear.

Transsexualism has now emerged as a more distinct diagnostic entity, and increasing numbers of transsexual patients have sought help from clinics. In general, societal attitudes have been fairly permissive, and it is becoming easier to fulfill many of the criteria that must be met before surgery can be contemplated. However, the cost of surgery ($4,000 to $5,000) constitutes a major obstacle. Further, few psychiatrists are prepared to recommend surgery unequivocally unless a series of important desiderata are satisfied, which may take several years. We will describe two cases of autocastration by male transsexuals who attended the gender identity clinic of the Emory University School of Medicine and the Georgia Mental Health Institute.

Case 1

Mr. A, a 25-year-old unmarried man, came to the clinic requesting hormones to prepare for sex-reassignment surgery, a course he had decided on at age 19. For the previous three years he had lived cross-dressed, used a feminine name, and obtained hormones intermittently from several physicians in the community. At age 2, he began to dress himself in some of his mother's clothes, and a maternal aunt is said to have cross-dressed him frequently. He played with dolls and became a "loner" when school began. Sexual activity was initiated in the preschool years by a male cousin 10 years his senior, and this relationship progressed to fellatio and anal intercourse at puberty. In all his sexual encounters he assumed the receptive position, and he denied any heterosexual activity, either real or fantasied. At age 10, he was referred by the school to a psychiatrist because he was shy and withdrawn. Therapy was brief, but he maintained episodic contact with the therapist over the next 10 years. At age 15, he started to wear makeup and earrings to school. At age 19, he cut his wrists while he was using amphetamines and was hospitalized for a short time. A diagnosis of paranoid schizophrenia was made then, largely because of his paranoid ideation about the inability of others to see him as a female. Treatment with chlorpromazine and psychotherapy for 1 year had no effect on his gender dysphoria.

On his admission to our clinic, physical examination and laboratory studies, including EEG, karyotyping, and plasma hormone levels, were all within normal limits. He felt very uncomfortable among homosexuals and thought he was not accepted by them. His main desire was to have dates with very masculine heterosexual men. He had no police record or evidence of recent drug abuse and denied having engaged in prostitution. There was no evidence of any psychotic process, unless one regards the fixed transsexual belief as a delusional manifestation of psychosis. He was capable of earning his living and passed very well as a female in the community. He was totally convinced that surgery would dramatically alter his life and explained that normal relationships were impossible for him because he was a woman with male genitalia. We began the feminization process slowly with controlled doses of estrogen and progesterone and monitored his plasma hormone levels by radioimmunoassay. He warned us he might castrate himself because he felt we were proceeding too slowly but said he could control the impulse since such an act might jeopardize subsequent genital

surgery. Soon after New Year's Day he went to a lavatory in a local hospital, injected lidocaine into the skin of the scrotum, incised the median raphe with a razor blade, excised both testes, and flushed them down the toilet. He stuffed a towel between his legs to control the hemorrhage and walked to the emergency room for further treatment. He had read about genital anatomy and had, with some skill, performed a bilateral orchiectomy. He called our clinic shortly thereafter and said, "I told you I would do it and I have." At this time there was no evidence of psychosis and the sensorium was clear. He felt no remorse or guilt and had no thoughts of further self-injury or suicide. With quiet satisfaction he stated, "No one can call me a man now." Twenty-one months later we supported this patient's request for full sex-reassignment surgery and, despite her somewhat bizarre lifestyle and obvious personality problems, she has made a satisfactory adaptation during the 12-month follow-up since surgery.

Case 2

Mr. B, a 23-year-old unmarried man, came to the clinic requesting sex reassignment surgery. He reported that he had castrated himself 2 years previously and had felt very much better since that time. For the past 3 years he had been taking feminizing hormones and had lived completely cross-dressed as a female. He described himself as having been feminine, quiet, and a "sissy" since early childhood. He cross-dressed at home before puberty without protests from his parents and began cross-dressing in public after high school graduation. His first homosexual intercourse occurred at age 14, and all of his subsequent sexual encounters were with men. He invariably took the receptive position. He denied any heterosexual desires or fantasies, but the fantasy of actually becoming a woman did not develop until late adolescence. He claimed to have had many sexual relationships with heterosexual men that lasted from a few to several months. He had castrated himself, following the simultaneous loss of both his job and boyfriend, after he took methaqualone tablets and drank a quantity of alcohol. Like the previous patient, he had acquainted himself with genital anatomy, but he relied on alcohol for anesthesia. He lost a considerable amount of blood, alerted his roommate, and was taken to a hospital. Despite his intoxication, he had placed the incision carefully in the midline of the scrotum, and the scar was quite difficult to detect. Psychiatric evaluation at the time of the castration did not reveal any evidence of psychosis; the patient expressed no regrets and felt no subsequent depression or anxiety. Psychiatric examination at the time of admission again failed to reveal any evidence of psychosis, and the diagnosis was gender identity dysphoria and hysterical personality disorder. This patient was strikingly feminine and had no difficulty passing as a woman in the community. We have provided her with hormones for the last 3 years, and 12 months ago complete penectomy and vaginoplasty were done at the patient's expense. Despite some emotional ups and downs, her adaptation has steadily improved and she has become quite successful in her career.

Discussion

These two patients demonstrate many of the features discussed by Blacker and Wong (1): they showed strong feminine identifications, an absent or uninvolved father during the formative years, a positive relationship with a dominant mother, and physical repudiation of their male genitalia. However, unlike the two schizophrenic men described by MacLean and Robertson (7) who performed self-enucleation, neither of our patients was thought to be psychotic at the time of the autocastration or thereafter. In 1976, Money and DePriest (3) described the only three cases of genital self-mutilation seen at the Johns Hopkins Clinic since 1951. Two of these patients were overtly psychotic, but the third case involved a planned autocastration by a 51-year-old transvestite. The authors noted that the autocastration did not result in any psychiatric deterioration. We believe that this act is qualitatively different from the self-mutilations occasionally seen in disturbed schizophrenics. Except in regard to their genitals the patients were not delusional, they had studied the anatomy of the area, did not butcher themselves, and had long-term goals that both eventually attained. Such patients perceive their genitalia as a severe impediment to effective social and sexual functioning. The penis and testes appear to be excluded from the body image by the male transsexual, probably as a result of years of continuing conflict between early feminine introjects and the peer and community responses to the individual as a male.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, comments on Association activities, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

"Hypohypomania" and Tricyclic Antidepressant Choice

SIR: Ample evidence suggests that tricyclic antidepressants, when indicated for unipolar depression, cannot be chosen at random. Some patients respond to amitriptyline (a serotonergic drug) and others to imipramine (noradrenergic), with little or no overlap between the two groups (1). To date, these groups are discriminable only by urinary 3-methoxy-4-hydroxyphenylglycol (MHPG) excretion or by response to *d*-amphetamine. However, MHPG assay is highly technical and not widely available, and many clinicians hesitate to use the widely abused amphetamines with outpatients, even briefly. Clinical guidelines such as agitation versus retardation, despite their popularity, lack discriminant value in controlled investigations (2). To avoid fruitless drug trials and prolonged patient suffering, the practitioner needs a means of distinguishing the two types of unipolar depression—amitriptyline-responsive and imipramine-responsive—that requires no more than the clinical interview. We would like to suggest such a method.

We have found by close questioning of patients diagnosed as unipolar that many have experienced episodes of increased energy and decreased need for sleep (even without increased sense of well-being), irritability in the absence of depression, and an increase in behaviors that in more full-blown form would obviously be hypomanic or manic (e.g., impulsive traveling, money spending, or making long-distance phone calls). These patients, many of whom were previously treated unsuccessfully with adequate courses of amitriptyline, have responded well to imipramine. They tend to have had earlier illness onset (20s to mid-30s) than patients who lack such histories. In this, they resemble depressed patients with distinct manic episodes (3). In contrast, patients without a history of these "hypohypomanic" symptoms (many of whom had received adequate imipramine trials) have responded well to amitriptyline. This guideline has successfully predicted the proper antidepressant in approximately 90% of 50 consecutive outpatients we have seen recently.

A recent study (4) suggested that one group of unipolar depressives, chosen on the basis of nonresponse to tricyclics, more closely resembled patients with more clearly developed bipolar affective disorder, but the authors did not say which tricyclics were used. Others (5) have noted that cyclothymic disorders represent a less severe point on the spectrum that ends in bipolar affective disorder and have emphasized the importance of searching for the more subtle symptoms of affective illness. Although both studies clearly document, on phenomenologic grounds, the nonhomogeneity of unipolar depression first suggested by MHPG studies, neither provides guidance for selecting a particular tricyclic.

One might determine on logical grounds alone, from extant studies, the correct tricyclic antidepressant for unipolar patients. There are two types of unipolar depression (1, 2, 4, 5): one responds to imipramine and the other to amitriptyline (1). Decreased MHPG predicts positive imipramine response (1) and depressed bipolar patients have decreased MHPG (2). Therefore, those patients with unipolar depressions who resemble bipolar patients, slight as the resemblance may seem, should respond to imipramine, while depressed patients without obvious or subtle hypomanic histories should respond to amitriptyline. Our recent experience supports this logic and has allowed us to predict, based only on the interview, the proper tricyclic antidepressant.

Mental Health Standards and Stereotype Traps

SIR: I have enjoyed reading the *Journal* for several years, but now I must register a criticism. I find it paradoxical and distressing that one author (Robert Butler, M.D., "Thoughts on Aging," July 1978 supplement) presented an articulate outcry against behavior that conforms to "society's norms or negative stereotypes," while another (Richard Green, M.D., "Sexual Identity of 37 Children Raised by Homosexual or Transsexual Parents," June 1978 issue) used "cultural

stereotypes" as criteria for implied psychological health. I am neither homosexual nor transsexual, but as a woman I shudder to think that my daughter would be considered "unfeminine," "neurotic," or "maladaptive" if her favorite toy were not a doll, her ambition were not to be a waitress, secretary, or nurse, or if she were interested in athletic endeavors (i.e., a "tomboy")—or that my son would be considered "unmasculine" if he enjoyed dolls and did not care for sports.

Certainly, differences of opinion on cultural matters are welcome and stimulating to your readers, but if psychiatry is attempting to attain scientific status it would be well advised to free itself of health criteria that are based on anachronistic cultural rules of behavior. In fact, many individuals throughout history have suffered loss of ego integrity as a result of being made to feel "abnormal" because they failed to fit cultural sex-role stereotypes. These stereotypic expectations have always been damaging among less sophisticated societal levels; to see them expressed in the *American Journal of Psychiatry* is very disappointing and—dare I say it—depressing.

Trifluoperazine and Haloperidol: Sources of Ejaculatory Pain?

SIR: Impotence is a known side effect of neuroleptic and antidepressant drugs, but I know of no published reports of ejaculatory pain resulting from either of these classes of medications. Thus it may be helpful to record the case of a patient who experienced ejaculatory pain when taking trifluoperazine HCl and when taking haloperidol.

The patient was a physically healthy 30-year-old father of two. I first met him when he was admitted to a hospital for an acute psychotic episode. He had been admitted once before, 3 years earlier, for the same problem. These acute psychotic episodes, as well as several temporary psychotic episodes, had apparently been precipitated by his use of marijuana. The patient said he had been treated with lithium carbonate during the previous hospitalization (the record is not available). He reported symptoms of feeling lost, getting messages from television, and, in general, feeling not himself. His wife added that his appetite and sleep were drastically impaired. Haloperidol, 15 mg/day, was prescribed. One month after admission the patient had responded and was discharged, still on haloperidol. The following month, he complained of fatigue and slurred speech and stopped taking the drug. Over the next months, he used haloperidol intermittently (approximately every 2 months) when he felt his symptoms returning.

About a year after his discharge, the patient suffered a particularly threatening episode of temporary psychosis. Nevertheless, he refused to resume haloperidol but agreed to a daily 10-mg dose of trifluoperazine. One week after taking trifluoperazine, he complained of pain on ejaculation. He described it as a deep, sharp pain experienced when the muscles contracted during ejaculation. The pain occurred whether ejaculation was induced by intercourse or by masturbation. He stopped taking trifluoperazine and 3 days later reported that he no longer experienced the pain. At that point, the patient agreed to resume haloperidol instead of trifluoperazine. However, on resuming haloperidol, 5 mg/day, he complained of the same pain upon ejaculation. As a result, haloperidol was discontinued. The patient had had a urologic examination 2 months after he was discharged, and no abnormality was found. Molindone hydrochloride, 50 mg/day, was substituted for the haloperidol.

In the more than 2 months since the patient has been on molindone, he has reported no pain on ejaculation and no other side effects. This raises the question of whether the pain was due to haloperidol or to trifluoperazine.

Psychiatry and Culture

SIR: Had I understood the article "Overview: Foundations of Cultural Psychiatry" by Armando R. Favazza, M.D., M.P.H., and Mary Oman, M.A. (March 1978 issue) it would not have been necessary for me to write this letter.

The authors assume that we all agree on a definition of "psychiatry." However, only about one-tenth of their article is devoted to "mental health and illness," so they must have had difficulty defining psychiatry. There is also some vagueness in their definition of "culture." Psychiatrists in general seem to rely, either from insecurity or pretense, on references outside their discipline. This may create the feeling that we are the first ones to see something new, making us innovators or discoverers. Why not quote the definition provided by Sir Aubrey Lewis, which would preserve and further the development and continuity of views and thoughts in psychiatry? Sir Aubrey, discussing the "ill-defined" concept of "culture," said it was "the sum total of persisting values, ideas, and other symbolic systems that shape the patterns of behavior" (1, p. 235). The last words in this definition are the link with our discipline. Closer to the roots of the word "culture" is a statement by Williams regarding its "main meaning of cultivation or tending, though with subsidiary medieval meanings of honor and worship" (2). The statement by Dr. Favazza and Ms. Oman that "the study of culture has not yet been established as a cornerstone of psychiatry" is misleading. Culture envelops psychiatry and psychiatry must find its place within culture—a place that will be different, and of varying importance, in different cultures. Mental illness may be looked at, assessed, and dealt with in varying ways. The authors have not dealt with these issues, and have ignored large areas of culture—art, literature, religion, and, particularly, history. If these areas had been included, then the discussion of the appropriate term might have had some justification. "Cultural psychiatry" at first glance might be superior to "cross-cultural" or "transcultural." My preference would be "comparative psychiatry," which implies that the psychiatrist, trained and working in one cultural sphere, moves to another and studies the existence and manifestations of psychiatric disorders therein.

The authors bypassed the first psychiatrist who undertook such comparative study, Kraepelin (3). The insistence on Freud's "Totem and Taboo" (4) and Jung's "Symbols of Transformation" (5) is hardly relevant to the study of psychiatric disorders today. Furthermore, there is a *petio principii* built into the paper: the authors quoted anthropologists and sociologists who rely on psychoanalytic and psychiatric findings to support their hypotheses, and then psychoanalysts and psychiatrists cite the same anthropologists, sociologists, and ethnologists, and these findings support their own theories.

The conclusion that the authors have reviewed prominent concepts and findings is an understatement. They did not mention Jaspers' *General Psychopathology* (6), which contains a section on "The Abnormal Psyche in Society and History." This section provides a glimpse of the relevant literature as well as indicating ways of making it important to the clinical psychiatrist. The strangest feature of their overview is that only the English literature—actually, only the American one—was quoted and even this was done one-sidedly. Could the authors not open their (and our) horizon a bit wider?

DIMITRIJE PIVNICKI, M.D.
Montreal, Que., Canada

Dr. Favazza and Ms. Oman Reply

SIR: In our article, we included only English language references because *Journal* editorial policy limits the number of references that may be cited. We chose what we felt to be salient references which would be available to most *Journal* readers. A number of our references are to books and articles that do provide an entrée into the foreign language literature. We think our approach in this matter was the proper one for an overview article. We did not discuss Kraepelin's Javanese data because we were not writing a historical article. As for the charge that we built a *petio principii* into the article, we can only deny it. *Res ipsa loquitor.*

We stated in our paper that we would deal with "concepts basic to psychiatry." Dr. Pivnicki seems to feel that our choice of child rearing and basic personality, cognition, family and social networks, sex roles and behavior, alcohol use, communication, and therapy are not basic psychiatric concepts because they do not fit in with his definition of psychiatry. Of course, we are all entitled to define psychiatry as we see fit, but our critic's definition would appear to be exceptionally narrow.

Dr. Pivnicki would have us further the continuity of psychiatric work and not reach out to anthropology or sociology. With this line of reasoning psychiatrists should also refrain from learning from biochemists, neurophysiologists, psychologists, etc. The study of culture is complex and complicated. If anthropologists, sociologists, and social psychologists have developed useful methods for studying culture, it seems unwise to reject this knowledge just because it was not produced by psychiatrists.

After reviewing over 3,600 mental health articles and books with anthropological or cross-cultural themes, we stand by our assertion that the study of culture, in comparison with the study of psychology or of the neurosciences, has not been fully established as a cornerstone of psychiatry. Dr. Pivnicki states that he learned little from our article. He is certainly to be congratulated heartily on his fund of cultural knowledge. We wish that all *Journal* readers were as well-read as he because it certainly would advance the sophistication of work in cultural psychiatry.

ARMANDO R. FAVAZZA, M.D., M.P.H.
MARY OMAN, M.A.
Columbia, Mo.

The Military Family: Who Has Been Scapegoated?

SIR: Nietzsche noted that every word represents a bias. Certainly a published study of opinion generalized from a small undefined military population in the midwest to the total military community, done without serious consideration of statistical tests of validity, reliability, and standardization, represents a subjective bias. My own experience and the relevant literature on the military family (1–3) fail to confirm the ideas presented by Don M. LaGrone, M.D., in "The Military Family Syndrome" (September 1978 issue). Such caricaturization represents the error of extreme views. The author stresses the inadequacy of intrapsychic models and professes an environmentalism that is startling in its simplicity. Do we need to remind the author that the individual personality is never determined by the group as a whole, and no individual is representative of all the characteristics imputed to any particular group?

The delineation of a syndrome in its simplest operational definition as a "set of symptoms which occur together" is not even attempted. There is an attempt to impugn all military families as in some way pathological by designating them as a syndrome. The idea that military psychotherapists should not treat disturbed military families and their children because they themselves are in the military is absurd and speaks to a peculiar belief system and environmentalism which holds that people in the military are less human than others.

Relevant published research on the military family that stands in contrast to the author's views was ignored (1, 2).

There is some indication that psychopathology in the military child tends 1) to run more toward ego restrictiveness and inhibitions than impulse-ridden behavior and 2) to be less frequent than that in civilian children (2, 3). The author states that the incidence of child abuse in the military is five times the national rate. This might be interpreted as a testimonial to good case finding, medical care, and reporting procedures rather than a negative indicator. Recent studies at Ft. Lewis, Wash., and San Antonio, Tex., suggest the opposite finding (4, 5). The San Antonio study found that while the military was 20% of the area's population, it accounted for only 11% of all child abuse cases (4, 5).

The author did not consider the possible confounding of his data by the high incidence of noncommissioned officers' families in his sample. What he designated as the child-rearing techniques of the military family are probably a function more of socioeconomic level than of the specific nature of the military milieu, if we regard it in the light of Kohn's classic study (6).

There is little substantiating evidence that scapegoating is more common in military families. The vague notion of a coalition between fathers and the military, with dependents

excluded as the third part of the triangle, runs counter to all we know of family relations. Certainly, the lower divorce rate in the military community would point to greater family stability. The military commitment to child care is represented in AR 600-48, which requires that every military installation of more than 2,000 dependents establish a child advocacy program for the purpose of monitoring and coordinating all programs and services for children: Dr. LaGrone ignored this. In that sense, the military is the only community which has attempted to implement the inherent philosophy of the 1970 report of the Joint Commission on the Mental Health of Children. If scapegoating is an issue in this paper, it is the military and the military family that have been scapegoated.

JON A. SHAW, M.D.
Washington, D.C.

Dr. LaGrone Replies

SIR: Dr. Shaw refers to Nietzsche's thoughts on bias and then betrays his own. His long list of complaints reveals an objection not just to what was said but to the fact that it was said at all. He seems to feel that an interactional model is too simplistic. I would suggest that an intrapsychic model is at least as restrictive and simplistic. I did not advocate an either-or stand with the use of theoretical models in my paper; I simply suggested that a systems model might assist the therapist in his understanding of military families.

There was no attempt to assign pathology to all military families, but I do feel that there are conditions in the military from which pathologic relationships might naturally evolve. The idea that military therapists should not treat military families because they are members of the same system is not absurd, and I believe the literature on family process would support my point.

Dr. Shaw refers to the "relevant" literature. I would ask him for the military definition of the word "relevant." While I was still in the military, I attempted to publish "The Military Family Syndrome." After eight attempts to have it cleared through "channels," I was finally told that it would not be cleared because "it would hurt the recruiting program." It was only after I left the military that I was able to send it to the *Journal*. Just how valid is military research when it is derived from a system that represses "unofficial" points of view?

Dr. Shaw implies that because there is a regulation (AR 600-48) for a commitment to child advocacy, this commitment actually exists. There is a difference. Perhaps Dr. Shaw would like to outline for us what actually has been put into practice and how effective it has been, using "statistical tests of validity, reliability, and standardization." Better yet, perhaps the military would do well to allow a neutral body of investigators to look at its mental health problems and to publish its report without repression.

Finally, there have been other studies that have reached conclusions similar to mine. Bloom's study was mentioned in my paper (1). Incidentally, his population was similar to the one in San Antonio that Dr. Shaw mentioned. White (2) studied a military population in Portsmouth, Va., and found that 59% of his patients were diagnosed as having a behavior disorder. The family dynamics he described were similar to those in my sample.

Psychotherapy or Consultation for Women's Conflicts?

SIR: In "Success or Failure: Psychotherapeutic Considerations for Women in Conflict" Carol Nadelson, M.D., and associates (September 1978 issue) discussed the conflicts experienced by many women today as they make career choices and the choice between a serious involvement in their work and family obligations. It has also been my experience that more and more women are facing career-related crises. I doubt, however, that the best source of help for these women is psychotherapy. To be sure, a short series of consultations may be needed to help some of them regain their balance or to ascertain that some are actually psychologically immature and have unrealistic expectations of work. In the case of married women, spouses should also participate in the consultation.

Prescribing psychotherapy carries the implication that a person is sick or has failed in some way because of her own conflicts. Actually, many of these women's problems are the result of their attempts to cope with adverse circumstances in a culture that is still highly ambivalent about women's success.

Many women have not internalized cultural values that assume that they, too, must achieve in the work world to realize their potential. This is further complicated by the fact that we know much less about female-male differences than we realize. More research in this area, free from cultural and political biases, is urgently needed if we are to avoid repeating the mistakes of the recent past in terms of men's and women's roles.

Like the authors, I see many single women approaching 30 who are torn between pursuing a successful career—for which one may need not only time but geographic mobility—and having a family. My view is that most of these women are no longer concerned about feeling deviant or different if they do not marry and have a family. Rather, they face a choice between satisfying their deep emotional needs to be part of a committed marital relationship and to have children and the realization that family obligations may pose a serious handicap to their career advancement. This dilemma was il-

lustrated in a recent article in *Fortune* magazine (1) which discussed a group of women who graduated with M.B.A.s from Harvard Business School in 1973. Some of them said they had decided not to have children; others who had children or planned to do so had given up ambitious career goals for which they are certainly as well prepared as their male counterparts.

Middle-aged women who opt for a career after raising a family are particularly vulnerable. Age *is* a handicap in the labor force unless one decides on a low-echelon job. I know women who are self-assertive, have the support of their husbands, and have prepared themselves adequately to enter the job market, but who cannot find suitable jobs or do not know how to compete in highly competitive arenas. Some of them end up accepting jobs that give them little satisfaction and that do not utilize their skills and qualifications. Others endure a life of discontent, unable to go back to their former emotional stance, to the times when they were looking forward to that "room of one's own" our society has been promising, and also unable to negotiate from a position of powerlessness. Their psychological paralysis, which is due to reality factors, is at the root of their depression and other health problems that seriously hamper their family and social relationships.

What these women need is not psychotherapy. They need to see consultants from the business and professional fields who are trained to present to them in a peer setting the realities they will confront, so they can make choices and plan realistically, according to their individual capacities and their emotional make-up. They need training in problem-solving strategies, in gamesmanship, and in realistic goal setting, and they need a working knowledge of the vicissitudes of upward mobility.

CLARA G. LIVSEY, M.D.
Baltimore, Md.

Dr. Nadelson and Associates Reply

SIR: We agree with Dr. Livsey that the problems of integrating career and family are complex and that alternative therapeutic approaches are indicated. We would, however, like to focus on some points where we differ.

We disagree with the idea that suggesting psychotherapy implies that the problem is one of illness. The importance of psychotherapy in facilitating coping or crisis resolution should not be overlooked. A person may use coping and defensive styles that are not in themselves pathologic but can be maladaptive to the new life situations presented by a career.

Conflicts that create difficulties in work achievement and satisfaction have long been considered appropriate for psychotherapy, which is then oriented toward facilitating successful adaptation. Traditionally, more men have been seen for problems centering around "work" and more women for concerns about "love." With recent cultural changes in roles for women, we are seeing more women who seek psychotherapy for conflicts about achievement and career.

We do not advocate that all women with work-related difficulties be seen in psychotherapy; we are making two main points in this regard. First, we are concerned that when reality issues concerning work are raised by a woman who is in psychotherapy the therapist consider them seriously and not see them as psychopathologic. Second, when a woman presents with symptoms (e.g., anxiety, depression, paralyzing ambivalence) concerning her work, which relate to intrapsychic conflicts and/or early life experiences and expectations, these should not be dismissed or seen as merely the reality problem of a working woman.

The career woman who experiences conflict between her commitment to her work and to her family may well seek and benefit from psychotherapy so that she can have a better understanding of herself and be able to find a more optimal situation. We do not believe, as Dr. Livsey implies, that family obligations necessarily impose a serious handicap on career advancement; on the contrary, the support and fulfillment of marriage and children may enhance one's energy and creativity. We heartily agree that research in these areas is needed. We believe that we must address issues of existing sex roles and their implications, as well as the process of formulation of goals and expectations for women. Although current evidence indicates that women are often conflicted and do experience role strain, we do not feel that this is a necessary condition.

A Call for Clarification

SIR: In his article "Psychiatrists and Physical Examinations: A Survey" (August 1978 issue), Charles W. Patterson, M.D., stated that Karl Menninger (1) has advised caution in performing physical examinations of psychiatric patients. This statement is potentially misleading because it does not refer to the fact that Dr. Menninger, in the very work cited, emphasized that "the Physical Examination of his patient is one of the psychiatrist's responsibilities and one of his professional privileges." He qualified this statement to reemphasize the obvious—that physical examinations are part of the relationship between doctor and patient and must be done tactfully. In fact, he even emphasized the positive effect a physical examination may have on a psychiatric patient when he stated that the examination "disproves the common error of belief that psychiatrists are only 'talking doctors,' not real, honest-to-goodness 'touching' doctors."

In actual practice, physical examinations are always done on the day of admission to the C.F. Menninger Memorial Hospital and in outpatient cases prior to assignment of a therapist partially because of Dr. Menninger's influence.

It is important to clarify this matter so as not to discredit Dr. Menninger and other well-rounded psychoanalysts and to avoid widening the artificial gap between psychoanalytically oriented psychiatrists and other psychiatrists.

Dr. Patterson Replies

SIR: Drs. Hamilton and Fisher believe that a statement in my article attributed to Dr. Karl Menninger is potentially misleading. They request it be clarified to avoid discrediting him. The statement in question was "Menninger . . . advised caution in performing physical examinations under certain circumstances because of potentially adverse consequences." Although Drs. Hamilton and Fisher do not indicate specifically how it is misleading, they may fear the reader will believe Dr. Menninger advises that physical examinations not be performed. They unnecessarily defend Dr. Menninger by quoting his statements about the usefulness of such examinations and by indicating the emphasis given to examinations at the Menninger Foundation. I did not state or wish to imply that Dr. Menninger advised against performing physical examinations; however, I am quite willing to have this point clarified.

The rest of their criticism reflects excessive sensitivity. They are concerned that lack of clarification could not only discredit Dr. Menninger but also "other well-rounded psychoanalysts" and widen the "artificial gap between psychoanalytically oriented psychiatrists and other psychiatrists." While my article does mention that the psychiatrist's future role is a topic of active speculation, it contains no criticism of "psychoanalysis" or "well-rounded psychoanalysts"; in fact, neither "psychoanalysis" nor "psychoanalyst" was mentioned.

Sex and Psychiatry

SIR: In my considered opinion the "sexual revolution" in psychiatry has gone much too far, and it is time to regain a sense of balance.

The *Comprehensive Textbook of Psychiatry* (1) deals with schizophrenia in 141 pages but devotes 260 pages to sexuality—a curious, if not absurd, ratio. In a recent article, Renshaw (2) advocated "the 30-minute sexological," during which the psychiatrist would demonstrate the structural and functional intimacies of the genital apparatus to couples with sexual problems who had obviously missed out on sex education.

Psychiatry has been repeatedly chastised for having moved away from the mainstream of medicine. One of the main stumbling blocks in efforts to develop a stronger identification with medical specialties appears to be the grandiosity of the psychiatric profession. In the last quarter of a century, American psychiatrists have been getting involved and claiming to be experts in many areas that go far beyond the boundaries of traditional psychiatry. The list includes poverty, crime, violence, education, politics, minorities, women's issues, and sexual problems. Since the basic training and experience of a psychiatrist does not endow him with special expertise in any of these areas, the image of the contemporary American psychiatrist is evolving toward "Jack of all trades and master of none."

The recent heavy involvement of psychiatry in problems of human sexuality is the latest example of this trend. I think the assessment and treatment of sexual problems belong to "sexology," which could be construed as a medical or even a nonmedical specialty but not as a subspecialty within psychiatry. None of the pioneers of sexology was a psychiatrist, and Freud certainly never advocated sexual counseling as the treatment of choice for sexual conflicts.

Masters and Johnson and other respectable sex therapists deserve our admiration, support, and referrals of appropriate patients. Let us separate sexology from psychiatry to everyone's benefit. Let sexual counseling and therapy be done by sexologists and let psychiatrists conduct psychotherapy. I for one am hoping to see the day when the American psychiatrist will return to basics and be expected to focus his efforts on patients with neuroses, psychoses, or character problems, where his training and experience enable him to be a true expert. There is enough work to be done in these areas to keep psychiatrists busy perhaps for centuries to come.

Monocytosis and Agranulocytosis Due to Neuroleptics

SIR: The article "Routine WBCs and Agranulocytosis in Children" by Leonard R. Piggott, M.D. (August 1978 issue) correctly reiterated the conclusions of Ayd (1), Pisciotta (2), and Litvak and Kaelbling (3) that routine interim hematologic surveillance is not very helpful in detecting incipient agranulocytosis during phenothiazine treatment. The physician familiar with its pathogenesis, knowing the rather anaphylactoid or apoplectic onset of so fulminating a disease as agranulocytosis, is aware of the relative uselessness of this measure. In 1965, however, I reported a probable relationship between the increased occurrence of monocytes in the peripheral blood of patients treated with chlorpromazine and chlorpromazine toxicity (4). It had been my observation that certain patients who demonstrated an increase of monocytes during chlorpromazine treatment had a relative intolerance and inadequate clinical response to this drug. This might reflect its toxic effect on the bone marrow, especially the myeloblastic series of it. I observed monocytosis beyond the individual norm prior to treatment most commonly with phenothiazines that belong to the chlorpromazine model group, which have in common three carbons in a straight chain (diaminophenothiazines), the group of phenothiazines most capable of producing agranulocytosis. I observed this trend to a much lesser degree with thioridazine but not with other phenothiazines, which in the same context are not generally associated with agranulocytosis.

The monocytic response appears to coincide with gradual intolerance or sensitization to the chlorpromazine model phenothiazines, culminating, in extreme cases, in the anaphylactoid response of agranulocytosis or pancytopenia, especially if it occurs with or is precipitated by virus infections or concomitant administration of other drugs (additive or potentiating effect). Although mechanisms of bone marrow suppression and antibody-mediated destruction of leucocytes (drug-dependent leukoagglutinating activity) have

been described, the pathogenesis of most cases remains obscure. An immunologic mechanism for WBC destruction is supported by strong evidence in cases involving aminopyrine, which shows some structural similarity to the chlorpromazine model group of phenothiazines and has a high potential for causing agranulocytosis.

The genesis and function of monocytes is not completely clear. Their chief function, apparently by virtue of their active motility and phagocytosis, is the removal of bacteria, protozoa, and substances that act as foreign bodies (lipoid substances, tissue debris, pigments). Tissue deposits of mentioned phenothiazines could be considered foreign bodies and explain in part the monocytosis, but my observation in two cases of agranulocytosis (4) seems to indicate that the increased number of monocytes prior to and following the agranulocytic stage may reflect compromised neutrophile function. A recent study (5) stressed the importance of monocyte functional capacity in patients compromised by granulocytopenia or neutrophile defects.

In the light of a possible causative relationship between monocytosis and chlorpromazine model phenothiazine toxicity on the hematopoietic system, a periodic white blood count, at least in patients treated with these neuroleptics, would become more meaningful and possibly more helpful to detect preclinically a predisposition to agranulocytosis. It would be of general clinical interest to test this relationship mentioned also for other drugs frequently associated with blood dyscrasia.

Passaic, N.J.

Dr. Piggott Replies

SIR: I appreciate Dr. Lutz's communication. The possibility that a monocytosis may herald an agranulocytic reaction is of considerable interest and may, if demonstrated in a larger number of cases, justify periodic white blood and differential counts on patients who are taking drugs which are known to have caused agranulocytosis. However, the actual incidence of agranulocytic reactions is so low that one would still have to consider carefully whether the chances of early diagnosis of an impending agranulocytic reaction would justify the expense and discomfort of repeated blood counts. Additionally, one must consider the possibility of finding false positive monocytic responses and the subsequent discontinuation of a needed medication. This might be of value in selected populations, such as women over 40, where there is a greater potential for the development of agranulocytosis. For the younger adults, adolescents, and children, where the reported incidence is exceedingly low, the routine use of predictive blood tests seems difficult to justify.

Still More on Dream Theory and Neurology

SIR: J. Allan Hobson, M.D., and Robert W. McCarley, M.D., are to be congratulated on their two stimulating and elegant papers, "The Neurobiological Origins of Psychoanalytic Dream Theory" and "The Brain as a Dream State Generator: An Activation-Synthesis Hypothesis of the Dream Process" (November and December 1977 issues). The authors arrived conceptually at formulations very similar to those I put forth in a paper delivered to the Medical Section of the British Psychological Society in June 1964 and subsequently published in an article entitled "A Review of Psychoanalytic Dream Theory in the Light of Recent Psychophysiological Studies of Sleep and Dreaming" (1). I subsequently developed these concepts further and discussed possible functions of the dream in a number of papers, chief of which were "Implications for Psychoanalytic Theory of Psychophysiologic Sleep Research" (2) and a chapter entitled "A Freudian View" in *Dream Psychology and the New Biology of Dreaming (3).*

I agree with some of the criticisms expressed in the series of Letters to the Editor in the May 1978 issue of the *Journal.* I do not believe that Drs. McCarley and Hobson were clear in their differentiation of the D state as a neurophysiologic state, the dream process, and the dream as a psychological or subjective event. Moreover, I cannot agree with their essentially linear attempt at interpretation of Freud's psychoanalytic (i.e., psychological) theory as deriving directly from his neurobiologic model in the "Project for a Scientific Psychology" (4).

In my papers, I emphasized that new neurophysiologic data required a revision of classical psychoanalytic theory, particularly with regard to the notions of dream process, and noted that "during the D state there are both heightened arousal and input of internally generated signals." I emphasized that thresholds for permitting external stimuli to reach the brain were raised and indicated (based on the evidence then existing and now more amply confirmed) that inhibitory impulses originating in the locus coeruleus essentially paralyzed the organism. Freud was aware of the importance of motor paralysis, although he had no notion of the actual neurophysiology: his first statement about sleep and dreaming in the "Project" emphasizes that in sleep one is paralyzed. I also pointed out that bilateral extirpation of the locus coeruleus in cats results in motor behavior during the D state, which suggests that the cats are acting out hallucinations.

As did Drs. McCarley and Hobson, I pointed out that new knowledge indicated that the D state occurred cyclically throughout every night's sleep. Hence, one could not conceptualize the motor force for the dream process as instinctual drives and infantile wishes becoming connected to memory traces of the day's residue. I also emphasized that Freud's notion of the dream as the guardian of sleep required revision and that in fact the evidence indicated that there are complicated neurophysiologic functions which operate to ensure that sleep is preserved under ordinary circumstances so that dreaming can occur. However, this is not to say that the dream as a psychological event, i.e., dream content, is

not determined predominately by memories and human drives or motivation. In a fashion similar to their notion that Freud's psychological theory or model evolved directly out of his neural model, Hobson and McCarley implied that the dream evolves almost as a direct event out of the neurobiologic state, although they did allow for psychological input into the dream. However, if one looks closely at their figures and concepts, it seems clear that they conceive of the signals generated in the pontine reticular formation as information, and they emphasize that the derivation of dreams is related to vestibular impulses. I have conceptualized this differently as the internally generating signals allowing a framework upon which psychological perceptions can be constructed. Evidence suggests that signals originating in the pons activate the lateral geniculate and then in turn the occipital cortex along with the general activation of the forebrain. Those neurons would perceive the signals as if originating in the retina. We know that when imprecise percepts are presented, such as Rorschach ink blots or tachistoscopic stimuli, the human organizes them into meaningful percepts. Because of the special quality of the D state, these are then raised to consciousness (what Freud calls "quality") and are perceived for the moment as real events. In this sense we would not talk of the direct dream generator but rather the dream process generator that enables psychological processes to develop the dream.

I have suggested that the internal signal generation by the pontine reticular formation, which reaches sensory areas such as the occipital cortex as if coming from external receptors, is a neurophysiologic process akin to Freud's notion of movement in a regressive direction in the mental apparatus during the dream process and activating the system perception from within. I share the notion of the dream as a synthesizing process.

A brief comment on the wish fulfillment hypothesis, which I have discussed in detail, is in order. Certainly, the infantile wish can no longer be conceived of as the driving force for the creation of a dream. However, when one samples human mental activity, either waking or sleeping, one finds evidence of motivation. Hence, the notion of wish fulfillment may not be entirely in error in that sense.

In my papers, I also discussed the evidence that much of the forgetting of a dream is to be explained as a state-dependent phenomenon. However, I do not believe we can eliminate the notion of repression entirely. Both with dreams of patients and in my own experience, I have noted that a well-recalled dream told to another person, whether analyst or spouse, is often then forgotten by the dreamer but not by the person to whom he or she has told it. In therapy the dream memory may return following appropriate interpretation. Freud himself changed his mind about the rapid forgetting of dreams. In the "Project" he explained poor memory by emphasizing that dreams follow old facilitations and thus make no change. Also, because of the motor paralysis, they leave no traces of discharge. Very shortly thereafter, in "The Interpretation of Dreams" (5), Freud took exactly the opposite position that the forgetting of dreams was inexplicable unless one took into account the resistance or censor.

Drs. McCarley and Hobson suggest that Freud's psychological theory was a direct derivation of his neurologic model. My own view is that in the "Project" Freud was trying to develop a neurologic model to explain his clinical psychological observations. He clearly gave it up as being premature in terms of the state of neurologic knowledge and turned to what is the basic psychoanalytic model, especially as elucidated in Chapter 7 of "The Interpretation of Dreams" (5). Clearly, most of the notions developed in Chapter 7 and many not mentioned after the "Project" for many years are to be seen in the "Project" (including some, such as issues concerning intelligence, with which Freud never dealt in psychoanalytic terms). This does not mean that these ideas developed as a consequence of a neurologic theory; rather, they were attempts to explain observed clinical behavior and communications. Strachey corresponded with me after reading my initial paper and it is clear that this was his notion as well.

In my view, much of psychoanalytic theory needs revision, and modern sleep research has indicated some of the necessary revisions. Freud's psychoanalytic theory derives by analogy from nineteenth century physics. He did not hesitate to use nonscientific analogies, as witness his brilliant paper, "Notes on A Mystic Writing Pad," which provides insight into the possible function of dreaming and anticipates the cybernetic notion of the brain as a computer. The necessity for constant revision of psychoanalytic theory does not rest on the notion that it grew directly out of a neurologic model. The most direct and erroneous derivation from the neurologic, in my opinion, is the literal notion of psychic energy, which clearly must be discarded. Unfortunately, space does not permit a greater elaboration of my ideas and their relation to those of Drs. Hobson and McCarley.

The Hobson and McCarley papers, in spite of needing some rethinking and revision, are elegant and draw on data unavailable 14 years ago, particularly their own brilliant studies on the mechanism of the sleep cycle oscillation. I wish they had searched the literature more carefully in preparation for their papers and had not presented their concepts as entirely new ones.

DAVID R. HAWKINS, M.D.
Charlottesville, Va.

Drs. McCarley and Hobson Reply

SIR: We thank Dr. Hawkins for the opportunity to call to the attention of *Journal* readers his and others' valuable contributions to the study of the relationships between physiology and psychology, both in Freud's writings and in modern sleep and dream research. Our paper on the physiology and psychology of REM sleep and dreams was not intended to be a claim that efforts at this kind of relationship had never been attempted before; indeed, we made repeated references to the efforts in Freud's day to make it clear that these attempts have a long and continuing history. They were especially common during the 1960s, when the first electrophysiologi

data about REM sleep became available. We were unable to cite many of these articles because of space limitations, and we are pleased to have the opportunity to point to additional discussions of the literature of this era (1–4). We wish also to reemphasize the importance of the works of Holt and Amacher that were cited in our paper.

Our paper was rooted in the conviction that advances during the past decade in the understanding of cellular and specific neurophysiology of REM sleep were sufficiently rich and complete to form a new theoretic orientation, to lay a foundation for specific interpretations about the relationship between physiologic and psychological events during dreaming sleep. Both of our papers emphasized this sense of a need for a new theory and a new orientation, a need that Dr. Hawkins and others evidently did not recognize. This is illustrated in Dr. Hawkins' summary statement and conclusion in the last paragraph of his 1966 paper (his reference 1), which stated that, while some revisions were needed, "the basic psychoanalytic theory of the dream process is in the main correct . . .," a conclusion far from our view. Indeed, all other previous psychophysiologic papers of which we are aware have concluded that little, if any, serious change in psychoanalytic theory was necessitated by the new data.

Dr. Hawkins' thoughtful letter makes clear further specific differences in theoretical viewpoints, which we will discuss below.

1. Freud's neurology and Freud's psychology: We are uncertain about Dr. Hawkins' exact viewpoint on Freud's "Project." Dr. Hawkins states at one point, "Freud was trying to develop a neurologic model to explain his clinical psychological observations," but he then states that "Freud's psychoanalytic theory derives by analogy from nineteenth century physics." We think this uncertainty over whether the project is a neurologic theory derived from psychology or a psychoanalytic and psychological theory derived from physics well illustrates our own viewpoint: Freud used the concepts of natural science (physiology, with its links to physics and chemistry) and those of psychology interchangeably because he thought that reconciliation of physical and mental concepts would be simple, or to phrase it more technically, that there were identity isomorphisms between the two domains. Now, 80 years later, it does not seem so simple, but we still believe in the fruitfulness of the search for isomorphisms between physiology and psychology.

2. Mind-body relationships: Do we confuse them? Our forthcoming paper on mind-body isomorphisms and the study of dreams (5) emphasizes and makes specific our concepts of the separate nature of psychological and physiologic data and theory. In it we state,

> The most useful strategy in the scientific study of mind-brain relations is to regard mind and brain concepts as coming from different linguistic and conceptual systems. In accord with the phenomenologists, we see the common origin of all percepts, whether of objects or of emotions, in raw experiential consciousness and suggest this initial event furnishes the foundation for elaboration of both mind and body or brain concepts. . . . We do not seek to reduce physiological to psychological events or psychological events to physical events. Nor do we view psychological events as causing physiological events or vice versa. Instead we view the proper strategy in mind-body study as seeking areas of contact between the conceptualizations of physiological and psychological theory. Mind-body isomorphism is our name for this strategy; it implies a conviction that such matching or mapping between operations and objects in the two conceptual systems of mind and brain can be found.

We have attempted to be extremely careful in trying to separate mind concepts from body concepts. Although it is entirely possible that we have erred somewhere in our discussion of mind and body and not kept these distinctions, we have attempted to avoid this pitfall and will be grateful to anyone who points out specific lapses of this kind.

We think the mind-body distinction is an important one and one that is too often blurred in everyday speech. Dr. Hawkins says something he might not mean when he notes that "neurons perceive the signals as if originating in the retina." Perception is obviously a psychological concept. Neurons may be activated in some way, but they never perceive, sense, or feel. Our way of phrasing it, and the way that is consonant with our specific theory of isomorphisms, is that the psychological concomitants of neuronal activation of the same temporal and spatial characteristics are the same, regardless of whether the stimuli come from the retina or from the brainstem. More abstractly, we would say that psychological event X is isomorphic to physiologic event Y, regardless of whether event Y is caused by physiologic event Z_1 or physiologic event Z_2.

3. The importance of the specificity gained by using information from cellular neurophysiology. Dr. Hawkins suggests that the signals the visual cortex receives during REM sleep are "imprecise," analogous to Rorschach ink blots. Unfortunately, at this moment neither he nor we knows exactly how precise or imprecise they are. The important fact is that this is amenable to investigation: our most recent physiologic studies, done in collaboration with Dr. Jack Nelson, suggest that the information received by the forebrain from the brainstem during REM sleep includes specific coding for laterality of the eye movements of REM sleep. We look forward to continuing physiologic investigation that will enable us to make more definite statements about whether the information is precise or imprecise. Another difference concerns the interpretation of the physiologic basis of motor behavior of cats who have lesions abolishing the muscle paralysis of REM sleep. Dr. Hawkins describes their motor behavior as "acting out hallucinations," a concept difficult to specify in physiologic terms. Our interpretation is that the motor behavior represents activation of various systems for patterned motor and instinctual acts, independent of visual system activation, and that the psychological concomitants of information about these motor commands during human REM sleep form an important dream substrate.

4. How does one assay the correctness of Freud's model of dream hallucinations in the "Project"? We think the only similarity between Freud's model as sketched in the "Project" and the current view of visual cortex excitation during REM sleep is that both regard it as coming from internal rather than from external sources. Three differences are particularly notable. First, there is no regression: Freud precisely and clearly defined regression as backward conduction of nervous activity. In fact, neurons conduct in their usual directions during REM sleep. Freud was writing at a time when there was no notion of the unidirectional nature of neuronal activation, which proceeds from the neuronal body down the axon. Second, Freud's concept of what is regressing to the visual system, i.e., "nervous energy," is not at all compatible with modern physiology and must also be viewed as an error. Third, even if one were to substitute neuronal activity for nervous energy, the source is not instinctual

wishes as Freud thought but motivationally neutral pontine activation. Thus in regard to conclusions about this aspect of Freud's theory, we leave it to readers to decide which of the following statements they prefer: 1) With the above exceptions, Freud's physiology of the visual system excitation during REM sleep was correct, or 2) Eighty years of work in physiology have rendered obsolete most of Freud's ideas on the physiology of visual cortex activation in REM sleep.

We do have important areas of agreement with Dr. Hawkins. Sleep research has indicated necessary revisions in psychoanalytic theory. We think that the impact of discoveries in physiology will become increasingly important and that interchange between physiology and psychology will grow as we become able to discover more and more of the physiologic concomitants of relatively complex psychological events. It is our hope to be able to present increasingly specific relationships between dreams and the physiology of REM sleep. We are thus taking up the long-abandoned tradition of Freud's "Project" and welcome a continuing dialogue with progressive psychoanalysts like Dr. Hawkins.

Withdrawal from Endogenous Opiates

SIR: In reading "Possible Withdrawal from Endogenous Opiates in Schizophrenics" by Michael Gitlin, M.D., and Michael Rosenblatt, M.D., (March 1978 issue) I was interested in the authors' observations on the possibility of "induced" withdrawal symptoms resulting from an interaction of naltrexone with the endogenous opiate system.

While I was with the National Institute on Drug Abuse (NIDA), I was Project Officer on the naltrexone development program and had the opportunity to have a continuing overview of all the patients who were taking naltrexone in the phase 2 research study. This included over 1,000 individuals who had taken at least a one-time dosage of naltrexone.

In September 1976 I coedited an NIDA research monograph on the progress of naltrexone development that included a paper entitled "NIDA's Naltrexone Research Program." In that paper I put forth the hypothesis for which Drs. Gitlin and Rosenblatt have now demonstrated possible confirmatory evidence. The relevant section read as follows:

> The only occasional side effect with some subjects seems to be an abdominal and gastrointestinal discomfort. When this was found at the beginning stages of treatment, it was attributed to minor withdrawal symptoms, because opiates were presumably still in the addict's system. However, these symptoms have been reported later on in treatment as well . . . .
>
> An intriguing scientific question, however, is: what interaction could naltrexone be having with the endogenously occurring opiate-like compound that has recently been isolated by researchers? Could, in fact, these abdominal symptoms be related to such an interaction? If an individual who is being maintained on naltrexone has a quantity of this endogenous substance secreted into his system and it is, in fact, opioid in nature, is it not possible to assume that some of the same symptomatology might occur as if an external opiate were entering this individual's system in a sufficient amount to cause such physical effects? This symptomatology might therefore include minor withdrawal symptoms characterized by the abdominal discomfort described. (1, pp 8–9)

I feel that this is an important line of research that needs further follow-up. We now have a glimpse into the possible interaction of antagonists with the endogenous opiates. This possibility should be pursued and further clarified. As narcotic antagonists evolve out of the research area and into the marketing/treatment area, we need to know how they might be affecting a naturally occurring human opioid system and what further ramifications such an effect might have.

DEMETRIOS A. JULIUS, M.D.
Tehran, Iran

Drs. Gitlin and Rosenblatt Reply

SIR: We appreciate Dr. Julius' correspondence. The NIDA monograph he coedited came to our attention after our paper had been submitted to the *Journal*. We are indeed pleased that our work has given preliminary comfirmatory evidence to Dr. Julius' hypothesis. The recent work of Watson and associates (1) replicating in a double-blind design the earlier work of Gunne and associates (2) which showed diminution of auditory hallucinations in a subset of schizophrenics given naloxone intravenously, further strengthens the importance of opiate antagonist research in the etiology and treatment of psychiatric disorders. A possible approach to clarifying this issue, one which we have incorporated into our present research, is to correlate withdrawal and/or therapeutic effects in patients given opiate antagonists with changes in CSF or plasma endorphin levels. However, given the conflicting data obtained to date in opiate antagonist research concerning both therapeutic (3, 4) and side effects only multiple investigations using varied protocols will help clarify these issues.

Correction

In the January 1979 issue there was an error in "Panic Attacks: Diagnostic Evaluations of 17 Patients" by Stephen F. Pariser, M.D., Bruce A. Jones, M.D., Emil R. Pinta, M.D., Elizabeth A. Young, M.D., and Mary E. Fontana, M.D. The sixth sentence of the Comment section should read, "Therefore, if MVPS is a cause of panic attacks, only 4 of the 17 patients would qualify for the diagnosis of panic disorder, because 6 patients who met other RDC for panic disorder also had definite MVPS."

Foundations' Fund Fellowships for Sabbatical Research in Psychiatry and Its Basic Sciences

The Foundations' Fund for Research in Psychiatry announces a limited program of support for scholars on sabbatical leave in order to further their research and contribute to the knowledge of psychiatric diagnosis, treatment, and prevention. The sabbatical must be spent away from the home institution at an internationally recognized institution.

Applications are open to distinguished and creative investigators with demonstrated research contributions in the field who hold full-time positions in professional schools and graduate departments of universities or equivalent institutes of research. Applicants must be U.S. or Canadian citizens or permanent residents of the U.S. or Canada.

The deadline for receipt of applications is May 1 of the year preceding the proposed sabbatical.

BOOK REVIEWS

The Psychopath in Society, *by Robert J. Smith. New York, N.Y., Academic Press, 1978, 157 pp., $7.80.*

Given the prominence of the diagnosis of psychopathy and the legal and moral questions it raises, the literature on the psychopath is relatively sparse. Prominent analysts of the caliber of Alexander and Karpman, along with Sheldon Glueck, have written on the subject, but the author states that Cleckley is the most charming to read as well as the most quoted authority. Cleckley views the psychopath "as basically insane, a sad creature who in spite of frequently superior endowment inevitably comes a cropper because of his failed moral development, dragging those who have trusted him down into the abyss of his own inevitable denouement."

Research on the subject has been confounded by casual labeling and the fact that the psychopath defies traditional mental health categories. The author notes that recognition of psychopathy as a specific disorder is typically dated to Pinel in 1801. In 1888 Koch introduced the idea of "psychopathic inferiority" in Germany and attributed it to hereditary weakness. Bleuler viewed psychopathic behavior as an emotional and moral deviation based on constitutional factors. Psychoanalysts are generally unsuccessful in treating psychopathic individuals because the analytic aim of loosening an overly strict superego is inconsistent with the fact that it is the psychopath's lack of inhibition that highlights his or her behavior.

In his second chapter, "The Charm and Winning Ways of the Psychopath," Smith notes that the psychopath's "most disarming aspect is a display of thoroughly beguiling charm." Sometimes aggression gets the upper hand, but even then there are flashes of charm that seem honest. Were he not a charmer, "he would be in no position to manipulate others, whether it is only to win a confidence or to use the other as perhaps a sexual or financial object." It is an innocent, even angelic, display that gives the observer a feeling that the psychopath is a person capable of full devotion and loyalty.

The search for a constitutional explanation for psychopathy, the subject of chapter three, has turned up very little if anything in the way of causation. In chapter four the author examines the social role and the learning theory formulations of psychopathy. In sharp contrast to those who seek an abnormality in bodily states stand those who view the individual as a product of his specific experiences of life. Something in the basic training of the sociopath is missing—the full steps of socialization have not been traversed. According to learning theory, the qualities of the sociopath come from imitation of a cold and distant parent, but Smith also discusses the paradox of how a psychopath manages to be so finely tuned to the needs of others that he can manipulate them.

In chapter five the author discusses "Cleckley and the Psychopath," noting that Cleckley is the recognized expert in the Anglo-American literature. It is not necessary to repeat Cleckley's concepts here; suffice it to recall the basic characteristics for his diagnosis: 1) superficial charm and good intelligence, 2) lack of remorse or shame, 3) untruthfulness and insincerity, and 4) pathological egocentricity and incapacity for love. As an example of psychopathy Smith describes Demara, who successfully posed as a politician, a naval officer, a psychologist, and a naval surgeon. The model thus posed for American psychopaths is, "Think big enough and the world can be yours."

In chapters titled "Psychopathy: Qualitative or Quantitative Entity?" "The Philosophy of the Marketplace and Psychopathy," "Psychopathy in Varied Cultures," and "Psychopathy and the Future" the author examines this condition, which is responsible for so much heartache and which plagued military psychiatrists throughout World War II. Smith cites Harrington's book titled *Psychopaths* (1), published in 1972, stating that Harrington took the fearsome view that the psychopath is the man of the future. Apparently, Harrington had written an article in *Playboy* as well, and Cleckley's withering comment on that article was, "Perhaps in this general and heedless effort to reverse the basic values anything traditionally regarded as undesirable or despicable might be stamped with the sign of approval."

The author discusses the views of other writers and of the counterculture. Little is said, however, about treatment. It was the opinion of Navy psychiatrists in wartime that the condition burns itself out when men get into their 50s. By that time parents have died and there is no one left to keep psychopathic individuals out of jail.

As to the present volume, I can recommend it for its complete survey of psychopathy. As I see the situation, it is pretty much the same as when the first edition of Cleckley's first book, *Mask of Sanity* (2), was published in 1941.

Organic Psychiatry: The Psychological Consequences of Cerebral Disorder, *by William Alwyn Lishman, B.Sc., D.P.M. Oxford, England, Blackwell Scientific Publications (Philadelphia, Pa., J.B. Lippincott Co., distributor), 1978, 967 pp., $75.00.*

In recent decades there has been a strong tendency for psychiatry to develop separately from internal medicine and neurology. This has been accompanied not only by changes in the theoretical and practical attitudes of physicians but also by the development of a clinical area that is usually referred to as a borderland, although the title No-man's-land may be more appropriate at times. *Organic Psychiatry* endeavors to cover this gap.

The author defines organic psychiatry as both a clinical

field and a clinical approach, with emphasis on the former. The first part (Principles) covers general aspects, such as the general psychological features of cerebral disorder, regional disturbances, clinical assessment, and differential diagnosis. There is also a section on terminology, although unfortunately the term "organic" is not further discussed. The second part, Specific Disorders, includes head injury, tumors, epilepsy, intracranial infections, cerebrovascular disorders, senile dementia and related disorders, endocrine and metabolic disorders, vitamin deficiencies, toxic disorders, and a final chapter on various other brain conditions leading to psychiatric illness.

The book is of course not a handbook that tries to be as complete as possible. Also, all topics are seen with emphasis on psychiatric rather than neurological or other medical aspects; this gives it a special flavor not found in most discussions of these conditions. The selection of material is not in all cases entirely clear, but the omission of specific child psychiatric disorders, for example, is explained in the preface as due to limitation of the author's experience. The emphasis on brain disorder results in some surprising but logical consequences: alcoholic disorders, for instance, are partly discussed in the chapter on vitamin deficiencies and partly in the one on toxic disorders, but a discussion of alcohol addiction and its social implications, as well as one of opiate addiction is missing. There are no illustrations, and the reader is usually referred to other works for technical details.

Within these confines—a postgraduate textbook of the psychiatric aspects of brain dysfunction in the adult—this book is excellent. It has the advantages of a one-author book, such as uniformity of purpose and style. The style, in fact, is lucid, and the book is a pleasure to read. The topics are extensively discussed vis-à-vis clinical features, etiology, pathology, and treatment, with a review of important publications. One particularly strong point is the presentation of many short illustrative case histories cited from the world literature. In his foreword, Sir Denis Hill states that "there is no comparable book in the English-speaking world," and a review of available texts would tend to confirm that opinion. He adds that it "will no doubt become standard reading . . . for postgraduate students of psychiatry and neurology." One may certainly wish this to be so (this might perhaps also result in a lower price).

The main problem with this work does not concern the author but the fact that it has evidently taken several years to print it, a fact that is somewhat surprising in this age of computers and space travel. This has resulted in the neglect of some recent developments; for example, there is only a very rudimentary treatment of computerized X-ray tomography. However, the text is carefully edited, and there are few errors.

Pediatric Psychopharmacology: The Use of Behavior Modifying Drugs in Children, *edited by John S. Werry, M.D. New York, N.Y., Brunner/Mazel, 1978, 399 pp., $19.50.*

The field of psychopharmacology in child psychiatry has begun to develop intensively in the last decade. The state of the art and science is now about where psychopharmacology for adult patients was about 10 years ago. This volume represents one of several recent studies. Dr. Werry has successfully pulled together some order out of the current chaos. He has coordinated the contribution of 13 contributors from 8 centers in the United States, New Zealand, and Great Britain.

Although many of the findings are now out of date, the overall coverage and the organization of the chapters of this book are commendable. In the first 5 chapters on basic principles, thoughtful contributions can be found on the biochemistry of the various compounds, pharmacological principles in children, research methodology, and some of the important ethical, social, and legal considerations in research and treatment. Dr. Werry puts the field into historical and cultural perspective in his introduction. His views on the scene in the United States from his vantage point in New Zealand are refreshingly direct.

The second part of the book contains chapters on individual drugs and their use in children 12 years old and younger: stimulant, antidepressant, antipsychotic, antiepileptic, antimanic, antianxiety, and hallucinogenic drugs, vitamins, and other drugs. The drug categories are borrowed from adult psychopharmacology only for the sake of convenience because the individual drugs are used for conditions in childhood that do not relate to the uses these adult-oriented categories imply. This issue is particularly well covered by Gittelman-Klein, Spitzer, and Cantwell in chapter five. The same chapter reviews the new diagnostic classifications in *DSM-III* and *ICD-9*.

An important message is advanced in the early chapters: investigation in the field of psychopharmacology for children should no longer be left to "amateurs." Several authors reiterate the need for careful, sophisticated, and rather complex research techniques. Cantwell points out that the best evidence so far supports drug use for target symptoms rather than for diagnostic entities. For example, imipramine is used extensively in enuresis and school phobia, lithium may be used to control hyperactivity or aggressiveness, and haloperidol has specific indications for the Tourette syndrome. About the only diagnostic entity for which medication is specific is the "attention deficit disorder with hyperactivity" (hyperkinetic syndrome).

Several of the authors touch on an explanation for the lag in development and the complications in applying psychopharmacological principles to child psychiatry. There is an understandable reluctance to give medication to young people. Perhaps even more important is the recognition that the developing child metabolizes and uses drugs differently at each age. Until very recently very few psychotropic medications have even been tested, much less approved for use in children.

The psychosocial aspects of medicating children are also touched on, such as the "overmedication" of children in certain school systems to control behavior, the use of medications in state hospitals, and the general tendency for adults to feel that they need to "do something" about childhood problems, sometimes at the expense of the child's real needs.

On the negative side the book is puzzling in that it aims at no specific audience. The editor says he hopes the text will be "comprehensible to any professional working or training to work with exceptional children." However, many sections are too advanced for neophytes. On the other hand, parts of some chapters are too superficial and brief for advanced workers or clinicians. In addition, clinical studies have already modified, negated, or replaced some of the findings reported.

The chapters on individual drugs provide a comprehensive baseline of knowledge. The editor has organized these well

so that each drug or drug group is reviewed in a systematic way under headings of chemical structure, pharmacology, clinical effects, side effects, drug interaction, clinical indications, "nonindications," and "contraindications," along with clinical administration and, when relevant, social and ethical issues. All in all, within its limitations the volume represents a good cross-section of a changing field.

PAUL N. GRAFFAGNINO, M.D.

Psychiatric Diagnosis: Exploration of Biological Predictors, *edited by Hagop S. Akiskal, M.D., and William L. Webb, M.D. New York, N.Y., SP Medical & Scientific Books (Spectrum Publications), 1978, 490 pp., $25.00.*

Only a few years ago psychiatric diagnosis was considered the hobgoblin of small minds. Psychoanalysts complained that diagnoses oversimplified the complexity of the individual patient, the Menninger school complained that illnesses were unitary rather than multiple, and scientific empiricists complained that diagnoses were too unreliable for use in research or good clinical care. This volume, the result of a three-day international neuroscience symposium devoted to the subject of psychiatric diagnosis, indicates that the tide of pessimism has reversed and that nosology has today become the preoccupation of many very fine minds. The participants include many of the leaders of modern psychiatry. Sir Martin Roth, Samuel Guze, Robert Spitzer, Jean Endicott, and Eli Robins are the first five contributors, for example, and their company is equally distinguished. The various contributions indicate that not only has psychiatric diagnosis regained intellectual and clinical respectability, it may indeed be the primary base on which scientific psychiatry must be built.

The presentations deal with four large subjects: clinical and biological criteria for psychiatric diagnosis, genetic principles in the classification of psychiatric disorders, biochemical and pharmacological correlates, and neurophysiological and neuropsychological correlates. Because the presentations were written primarily by investigators who have done pioneering research in each of these areas, they provide a comprehensive survey of current knowledge in psychiatry that also seems fresh and exciting. Distinguished "experts" sometimes become careless or casual when asked to write a survey of their own and related work, but that is not the case with this group. Nearly all of the contributors have taken care to write clear and informative reviews of their particular areas.

The volume leads off with an impressive discussion of the entire field of psychiatric diagnosis by Sir Martin Roth. He touches succinctly and thoughtfully on such various subjects as mathematical and computerized approaches to diagnosis, categorical versus dimensional approaches, the relationship between etiological and symptomatological classifications, research versus clinical classifications, and the assessment of reliability and validity. Guze discusses the important contributions of the "St. Louis school" to the definition and validation of diagnostic categories, and Spitzer, Endicott, and Robins describe their successful efforts to improve the reliability of psychiatric diagnoses. Corbett reviews specific problems in the definition of affective and schizophrenic syndromes, and Akiskal and associates review the methodological problems inherent in developing a system that is both clinical and biological and then apply this methodology to the description of cyclothymic disorders.

Genetic and family studies have provided powerful input for the development of modern nosology. Their contribution is summarized in a second set of papers. Matthysse and Kidd, both basic behavioral geneticists, describe the two mathematical models currently used most frequently to formulate genetic hypotheses, the multifactorial model and the single major locus model. Rosenthal gives a lucid summary of his work with Kety and Wender, using the adopted offspring method to explore the possibility that schizophrenic disorders form a spectrum. Cadoret and Cloninger present data suggesting that alcoholism and affective disorder may also form a spectrum, as may hysteria and antisocial personality.

The final two sections cover topics of equal importance by equally distinguished investigators: Dunner and Fieve on the impact of lithium on diagnosis, Carlsson on the neuropharmacology of schizophrenia, Janowsky and Davis on physostigmine and methylphenidate challenge tests, Wyatt and associates on platelet monamine oxidase, Meltzer and associates on neuromuscular dysfunction, Goodwin and associates on pharmacological differentiation of affective disorders, Lang on the psychophysiology of anxiety, Hartmann on sleep patterns as biological predictors, Buchsbaum on average evoked potentials, Lehmann and Ban on design issues in experimental approaches to diagnosis, Tucker and Silberfarb on neurological dysfunction in schizophrenia, and Whybrow on neuropsychology.

As a diagnosis "maven" myself, I anticipated reading this book with a bit of boredom. Instead, I was pleasantly surprised and usually read with interest and even excitement. It discusses most major issues currently relevant to the development of diagnostic systems and explores the various biological and psychological correlates that may be used to validate them. In general, each chapter is a clear summary of current thinking in a particular area. To be sure, some important areas have been overlooked, such as social factors, personality factors, psychological testing, and neuroendocrinology. In general, the editors have opted for a more "biological" perspective. The book is an excellent one overall. I recommend it for academicians and clinicians alike—for anyone who would like a brief but comprehensive overview of changes in diagnostic practice and the scientific rationale behind them.

Iowa City, Iowa

War on the Mind: The Military Uses and Abuses of Psychology, *by Peter Watson. New York, N.Y., Basic Books, 1978, 522 pp., $20.00.*

This book is a definitive account of the development and use of psychology in the military. Peter Watson, who is both a psychologist and a journalist, skillfully explores an area about which most psychiatrists have a cursory knowledge at best. Watson's research uncovered 7,500 studies published in this subject area since the end of World War II (more than 1 a day). Of the 146 organizations involved in military psychology around the world, 130 are in the United States. Only 80 of these belong to the Armed Forces. The rest are private, university-based, or hospital-based institutes or think tanks.

The author reviews the original involvement of military psychology in matching soldiers with military machines, training military specialists, and selecting troops. He then reviews psychology's involvement with "paramilitary"

areas—counterinsurgency operations, motivational studies of guerillas, the sociological and psychological effects of economic underdevelopment, and human factors in clandestine organizations, to mention a few.

In his introduction the author raises a number of provocative issues. In the following five sections he deals with different aspects of military psychology: combat, stress, determinants of loyalty and treason, survival, and the psychology of counterinsurgency. In these five sections the author is dispassionate and objective. Although he acknowledges his own occasional antimilitary feelings, he strives to give a reasonable account of both the good and the bad, the constructive and provocative (or dangerous) studies in each category.

Watson discusses the concern that secrecy unavoidably leads to poor methodology as well as useless and/or unreliable results. Without scientific interchange among scientists and without scrutiny by professional colleagues, a study's results can be disastrous. Watson notes that President Johnson escalated the bombing in Viet Nam on the basis of a psychological study by a prestigious organization that predicted the Viet Cong would succumb to a small amount of additional force. Watson also discusses a new technology that would link a pilot's brain to a computer so that the pilot would be able to fire and guide a missile to a target by thought processes. Finally, he describes the problems that arise when we do not know how to use the information we develop.

In his conclusion Watson posits that the popular fears of "psywar" or "mind control" are exaggerated. The vast majority of esoteric psychological experiments fail; instead, scientists explore the control of human behavior in war. In a discussion of war psychology versus peace psychology, Watson points out how studies of leadership, weapon effect, risk-taking, and survival can all be used to strengthen our efforts for peace. He urges more collaboration between military and nonmilitary psychologists and a decrease in the amount of military secrecy.

Although nationalism dictates that a nation's resources be used for its own survival, Watson proposes an international association of military psychologists to foster openness and collaboration among scientists. Research in this area need not increase the likelihood of war nor be abusive, but open scrutiny on an international level is necessary to ensure results that benefit mankind.

In this fascinating but at times tedious volume, Peter Watson challenges our profession and our society to be aware of the potential of the various psychological sciences and to use them for the best interest of all nations. This is not a book that everyone need read. However, the introduction and the conclusions contain information that behavioral scientists should possess in order to understand the full implications of the work in which we are involved.

The Endorphins. Advances in Biochemical Psychopharmacology, Vol. 18, *edited by Erminio Costa, M.D., and Marco Trabucchi, M.D. New York, N.Y., Raven Press, 1978, 366 pp., $28.00.*

This book contains the material presented in Brescia, Italy, on August 28–30, 1977, at a symposium on endorphins. It seems that the papers were printed just as they were received; when an editor or, more probably, the publisher, found a typo or a poorly chosen word and replaced it, the replacements were made with a different type than the original. Raven Press has, with only a few exceptions, avoided using camera-ready copy; it should continue to do so until it has mastered such techniques as correcting authors' manuscripts and placing tables and figures well (e.g., after, not before, their citation).

With regard to the contents of this volume, the selection of topics and authors is very good, as is the coverage of most aspects of endorphinology—from the original concept of the existence of endorphins to the work in progress in the summer of 1977. Some chapters contain sufficient details of the laboratory techniques to allow the reader to reproduce the studies (a chapter by the Johns Hopkins group even gives the name and address of suppliers of nonstandard items). Others only guide the reader into the rapidly exploding literature on the endorphins. The literature references are current, as they have to be in this new field.

In the preface the editors use a phrase that, at least to me, exemplifies a current problem in pharmacological semantics: "endogenous ligands . . . function as putative neurotransmitters." Nothing, but nothing, can function as a *putative* neurotransmitter. Although a few authors misuse the naked term "neurotransmitter," more and more are abusing the modified "putative neurotransmitter."

A chapter by Floyd Bloom and his colleagues at the Salk Institute on the cellular localization and electrophysiological and behavioral effects of β-endorphin exemplifies what is good and what is poor in this volume. The authors are leaders in the field, the references include many papers so recent that they were still in press when this book was published, and the figures are adequately printed so that the reader is able to discern the point at issue. However, typographical corrections are blatantly inserted in different type from the original, and 20 or so errors were not corrected. Putting aside these nit-picking points, the reader will find one of the clearest descriptions of the methodology used in immunocytochemical studies (except that the tense goes back and forth from past to present) and one of the most thorough listings of regional distribution of endorphins to be found.

After making allowances for the fact that there is no table of abbreviations even though authors use different abbreviations for the same compound and some authors do not define their abbreviations, and for the fact that some authors presume familiarity with the field and others assume only general knowledge, I have to recommend that anyone interested in endorphins obtain a copy of this book and have it available on his or her bookshelf because it represents the best available review.

EARL USDIN, PH.D.[1]
Rockville, Md.

Explorations in Psychoanalysis, *by Ralph R. Greenson. New York, N.Y., International Universities Press, 1978, 560 pp., $22.50.*

Collections of the contributions of eminent psychiatric and psychoanalytic authors provide readers with a convenient way to systematically survey a coherent body of work or the evolution of an idea or point of view. *Explorations in Psy-*

choanalysis is an aptly titled sampling of the writings of an outstanding teacher and clinician covering more than 40 years of psychoanalytic investigation. The papers are offered in chronological sequence and are derived from extensive clinical experience with a wide variety of patients. Each illustrative vignette is a model of succinctness, vividness, and recognizability. Indeed, the first dozen papers read like the reports of a dedicated naturalist or anthropologist, an observer of the human scene recording his findings as he probes deeper and deeper into a new land.

Greenson's studies of "The Psychology of Apathy," "On Enthusiasm," "On Phobia, Anxiety and Depression," and "On Gambling" earn him recognition as the de Tocqueville of the realms of neurotic phenomenology. As a result, the reader is provided with a comprehensible and demystifying guide to the understanding of patients with related problems. In each instance Greenson adduces the relevant insights afforded by psychoanalytic psychology and psychopathology and details the characteristic appearance and behavior patterns of the types under observation.

Most of the papers deal with specific problems of technique. Greenson suggests that this volume be considered a companion to his 1967 textbook (1), but it is immediately clear that a great many of the clinical and theoretical topics discussed bear closely on every aspect of psychotherapeutic work. An appropriate emphasis is placed on transference and countertransference phenomena. The author documents the necessity for a continuous scrutiny of the way in which the therapist relates to his or her patient. He underscores the crucial verbal and nonverbal communications from the patient that arise in response to fluctuations in this interplay. The way in which neglect of any of the varied aspects of transference, subtly present in every clinical moment, can seriously jeopardize understanding and therapeutic effectiveness is brought home in many convincing demonstrations. After repeatedly stressing the ubiquitousness of resistances that complicate any therapeutic effort, Greenson draws together a host of pertinent insights in a discussion of "The Problem of Working Through."

It should be noted that Greenson places great emphasis on his concept of the "working alliance." This formulation, related to Zetzel's use of the term "therapeutic alliance" (2), has had a far-reaching impact on psychotherapists and students of the theory of therapy. Its appearance in this volume gives us an opportunity to examine the ideas involved in the context of Greenson's papers on technique.

It seems to me that the central argument and the clinical illustrations offered in support of the working alliance are not entirely convincing. There is considerable question as to the value of separating the concept of a working alliance from that of the transference neurosis. The disadvantage of treating the resistances encountered in a patient's dealings with the therapist and in the conduct of the therapy itself as special problems is that it can lead to the belief that they are derived from something other than the patient's active psychic conflicts and must be handled in a unique way. In many instances the idea that a favorable climate for therapeutic work must be fostered by the therapist's behaving in a more "human" manner promotes interventions and expectations that do not advance an adequate understanding of the clinical situation at hand.

Mention should be made of one of the highlights of this valuable volume, Greenson's review of the fourth volume of *The Writings of Anna Freud*. It is a brilliant expression of his appreciation of and admiration for the contributions of Anna Freud, whose interests, particularly as they are expressed in these writings, are in many cases paralleled by Greenson's own. He succeeds in demonstrating how her papers of the period 1945–1956 reflect and clarify many clinical and theoretical developments in the burgeoning field of psychoanalysis. Because Greenson's extraordinary talents as a teacher and clinician are evident throughout this work, the book can be heartily recommended to anyone interested in psychotherapy and human psychology.

Great Neck, N.Y.

Principles and Practice of Child Psychiatry, *by Stella Chess, M.D., and Mahin Hassibi, M.D. New York N.Y., Plenum Press, 1978, 486 pp., $20.00.*

In the first chapter of *Pragmatism* (1) William James proposed the now well-known separation of "tough-minded" and "tender-minded" philosophers. He described the tough-minded thinkers as devotees of empiricism, who liked pluralistic classifications based on observation and remained skeptical of anything beyond factual data. In contrast, the tender-minded thinkers were adherents of rationalism, who used reason to build speculative systems of abstract, unifying principles. James's dichotomy of thinkers is not only applicable to philosophers, as James himself was aware, but may be extended to a variety of disciplines that are enriched by the counter-play of both orientations. Psychiatry may be seen as having its "tough" clinicians and "tender" theorists perhaps Kraepelin and Freud could serve as notable paradigms. The subspecialty of child psychiatry is no exception to this bifurcation of orientations. The works of Frederick Allen, Erik Erikson, and Anna Freud, which concern themselves with expounding a general philosophical position, are balanced by the contributions of Leo Kanner, Loretta Bender, and Michael Rutter, which concentrate on the documentation of clinical fact.

This new book by Chess and Hassibi may be viewed as firmly in the tough-minded heritage and as exemplifying this tradition at its best. The authors adopt the viewpoint of an unbiased clinician, sticking close to the observable data and refraining from espousing any theoretical prejudice. The volume is divided into four sections. The first section presents an introduction to the field by tracing the history of childhood, documenting the course of normal development, and summarizing the major theories of development. The writing is straightforward and clear, with ample references to important studies. The second section is concerned with general concepts of psychopathology in childhood, stressing the various etiological factors culminating in a multicausal model of illness that requires comprehensive assessment. The third and longest section deals with particular syndromes of child psychopathology. These chapters are mainly phenomenological, listing symptom complexes in textbook fashion. The major contributions are cited and theoretical views noted in an objective and, at times, appropriately critical manner. I especially appreciated the inclusion of chapters o

physically handicapped and gifted children, two potentially at-risk groups that have not received sufficient attention. The last section covers treatment and prevention. Some readers may find the space allotted to individual psychotherapy somewhat short and skimpy, but the relatively brief presentation of this therapeutic dimension may reflect the authors' concern with the larger perspective of promoting child mental health, including prevention and methods of service delivery.

Chess and Hassibi have managed to compile concisely and clearly an impressive amount of information. As they mention in their preface, they were aided in the formidable task of covering so vast a field by noted authorities who graciously read and commented on selected chapters, thus adding the benefit of their expertise to this work. Aside from the documentation of extensive material, the impressive aspect of this book is the respect the authors show for the complexity of child development and psychopathology. Throughout the work the reader senses the wisdom gained through extensive clinical experience, which teaches that each child is an individual. The modest tone of the authors is certainly to be applauded. Chess and Hassibi often remind the reader of how much we still do not know about children's psychological health and illness. However, much of what we do know can be found in this book.

Habilitation of the Handicapped: New Dimensions in Programs for the Developmentally Disabled, *by Marvin Rosen, Gerald R. Clark, and Marvin S. Kivitz. Baltimore, Md., University Park Press, 1977, 366 pp., $18.50.*

Although the title of this book uses the broader term "handicapped," its major thrust is the treatment and management of mentally retarded people. This topic is sequentially presented in a series of 21 chapters arranged into seven sections. Each of the section titles focuses on a key issue, such as the nature of the habilitation process, institutional versus community-based challenges, and the major components of modern programs that can alleviate social and emotional deficits.

The nature, goals, and problems of the habilitation process in mental retardation are clearly presented in the first two sections. A succinct overview follows of the contemporary trend of deinstitutionalization, with particular reference to its reality underpinnings. For example, the world literature concerning follow-up studies of formerly institutionalized retarded citizens clearly documents the key reasons for failure in community placement—social and emotional factors (not the type or level of mental retardation). In the following two sections the authors present their research findings on key aspects of these social and emotional factors: self-concept, helplessness, and the personality residuals of excessive acquiescence. Next, an excellent section focuses on how to implement some very innovative treatment methods and management techniques for alleviating these deficits. By summarizing the entire book, the last section clearly articulates the current movement away from the late intervention of intellectual and emotional deficits (i.e., rehabilitation) to the initiation of developmentally oriented programs that can foster optimal developmental goals (i.e., habilitation).

This book is an excellent review and a clear presentation of the available modern approaches to maximizing the developmental and psychosocial dimensions of the mentally retarded in the United States. Accordingly, I highly recommend it to colleagues who include the care and treatment of retarded citizens in their clinical, teaching, and research careers in psychiatry.

FRANK J. MENOLASCINO, M.D.
Omaha, Neb.

International Review of Research in Mental Retardation, Vol. 9, *edited by Norman R. Ellis. New York, N.Y., Academic Press (Harcourt Brace Jovanovich), 1978, 298 pp., $23.00.*

This volume is the latest in a series directed to psychological investigations in the broad field of mental retardation. It covers information processing studies and their implications for the care of the retarded, with several sections on labeling, psychophysiology, and biological defects as well as a group of reports on services for the retarded; there is also a chapter on idiots savants. The authors are established workers in psychology and special education; all 15 of the contributions come from American authors, although the title implies an international overview. The school and community experiences in normalization are also from the United States.

The book begins with the accurate notation that the climate for research in retardation is currently poor and that federal spending and the national emphasis on "breakthroughs" have led to disappointment. It examines studies of deinstitutionalization, mainstreaming, and the problems of placing the retarded in schools and in the general community. The papers include classically academic psychological studies in the mental processes of the retarded, addressing many of the basic problems in conceptualizing memory and learning processes. They review current issues under investigation in universities in the United States: masking, iconic memory, visual persistence, sensory storage, and scanning.

The results are not exciting; the conclusions cluster around such statements as, "The retarded are characterized by a lag in the development of certain central processes, rather than a structural defect in their processing systems" (p. 15). Another author concludes that research has been "both provocative and disappointing" (p. 24).

There is little psychodynamic contribution to these studies, although they do reveal the state of academic research. Direct applications for professionals dealing with the retarded are hardly addressed. However, the review of alternatives to residential care are based on actual experience. They are easier for clinicians to appreciate and indicate how the rhetoric of "normalization" has been biologically naïve and socially illusory. The resistance of teachers, students, and school administrators to the integration of retarded children into their classes is poignantly documented and clearly delineated. There are helpful data about the many types of facilities for the retarded and the myriad ways in which the definition of group homes, semi-independent units, and protected environments will determine the funding and function of these facilities.

The work has sections of great interest to psychologists,

teachers, and community psychiatrists who deal with retarded populations and has value for considering the ways of getting psychiatric patients out of hospitals into community settings. It also provides a good "state of the art" cross-section of the psychological investigations in mental retardation. Overall, it can be viewed as a sound reference volume for specialists.

Chicago, Ill.

Social Skills and Mental Health, *by Peter Trower, Bridget Bryant, and Michael Argyle, with John Marzillier. Pittsburgh, Pa., University of Pittsburgh Press, 1978, 301 pp., $12.95.*

This book is a volume in the Contemporary Community Health Series of the University of Pittsburgh Press. It was written by the research and project staff of the social skills research project of Littlemore Hospital, Oxford, England. The book consists mainly of a careful review of the literature on various interpersonal and social skill development techniques and a manual for assessing social deficits and training clients to improve these deficits.

A large number of techniques for improving social skills have been developed over the past decade. A number of these involve interpersonal skills—verbal and nonverbal communications, assertiveness training, and decision making. These skills are especially needed by individuals who are socially inadequate as a result of passive, inadequate, or asthenic personalities. *Social Skills and Mental Health* reviews the literature concerning the effectiveness of training programs to remedy these interpersonal skill defects and then outlines in manual form the program developed at Littlemore Hospital.

The review of the literature in the area of interpersonal behaviors is excellent, including listening, observing, speaking, asserting, planning, and how these can be taught. This area of skill training is important and must be given greater attention as we move to carry out more mental health services in the community; it will be especially needed for chronic mental patients returning to their communities after years of hospitalization. However, it appears that some of these techniques may not be as effective with chronic patients as they are with individuals with inadequate personalities who come to outpatient clinics. One wonders why these rehabilitative training programs are referred to as "therapy," but this is a fine point because they are important.

The second part of the book, the manual for assessing and teaching interpersonal behavorial skills, is very specific and graphic. It should be of great use to those who work in mental hospitals, halfway houses, social rehabilitation programs, and community mental health centers oriented to developing social skills.

Living in Prison: The Ecology of Survival, *by Hans Toch. New York, N.Y., Free Press (Macmillan Publishing Co.), 1978, 310 pp., $12.95.*

The subtitle of this book is appropriate. Anyone who has had the experience of working directly with inmates will find the concepts so vividly portrayed by the author and his coworkers familiar. Hans Toch has succeeded in communicating the stresses of prison life as seen by inmates in several well chosen institutions.

The greater part of the text is based on inmate interviews illustrating how the environment of the prison is perceived by the individual. From these interviews the major areas of concern are spelled out: safety, freedom, activity, privacy, structure, support, and feedback. After reading the inmate interviews, one certainly feels that the word "concern" is an understatement. The author views the importance of each of these concerns in a transactional framework; each depends on many variables but mainly on inmate personality and institutional setting.

The author shows that by listening to each inmate one can make better choices in the classification process. Ideally, each inmate would have extensive testing and interviews to evaluate his adaptive strengths and weaknesses to enable one to match him to the proper institutional environment. Admitting fiscal restraints, Toch and his team have developed a Prisoner Preference Profile to assist in the classification process. The last chapters of the book examine the validity of the Prisoner Preference Profile to the extent that the results of the inventory make sense in terms of whatever else is known about the inmate.

Age, ethnicity, marital status, and other demographic data correlated well with inmate concerns. For example, older inmates were less concerned with freedom than younger inmates. The comparison of each of the demographic variables with each of the inmate concerns seems to validate the instrument for use as a time-saving device in the classification process.

The inmate interviews excerpted in the text are certainly valuable in the sense that they serve to describe and explain the development of the Prisoner Preference Profile. They are just as valuable in giving the reader a sense of the tremendous impact of the prison environment on incarcerated individuals. The section on stress and its amelioration and especially the chapters on "Niches in Prisons" and "Living in Protection" should be read by anyone who works in the correctional system and may be called on to make decisions relating to the health and well-being of inmates. One has to know the right questions to ask inmates with symptoms of anxiety, depression, or other indicators of defensive structure. In many cases the answers are found by searching out with the inmate his concerns about the prison environment. The author has given us an appreciation for the real feelings of prisoners and their attempts to adapt to and change their prison environment.

DAVID L. HEDBERG, M.D.
Hartford, Conn.

Consciousness and Self-Regulation: Advances in Research and Theory, Vol. 2, *edited by Gary E. Schwartz and David Shapiro. New York, N.Y., Plenum Press, 1978, 428 pp., $22.50.*

Reviews of basic research ordinarily permit only limitec extrapolation to the clinical setting. *Consciousness and Self-Regulation, Vol. 2,* however, contains in several of its 1(chapters a surprising amount of information relevant to psychiatric practice.

Pope and Singer's chapter, "Stream of Consciousness,' for example, reviews research in attribution theory, attention-focusing, and memory selectivity. These areas, impor-

tant for psychotherapists who would consider themselves scientists as well as artists, are embarrassingly unfamiliar to most psychiatrists. Pope and Singer reject oversimplified explanations of cognition, including the psychoanalytic denigration of primary process as immature thinking.

Although the concept of repression has generally not fared well in the hands of researchers, Sackeim and Gur do moderately well by it. They methodically forge a case in support of self-deception as a genuine phenomenon. In the key experiment, subjects who often misidentified their own voices on audiotape also evidenced autonomic changes that implied accurate self-recognition.

After demonstrating that the cognitive factors affecting eating behavior are manifold, intricate, and interactive, Rodin emphasizes the fragility of self-control in individuals with weight problems. The fundamental difficulty is presumed to be either constitutional or developmental. Fat people—even formerly fat people—show heightened sensitivity to external cues, including nonfood cues; however, they seem impaired in their ability to generate images entirely from imagination. Some of Rodin's data appear compatible with the fat-cell theory of hunger, which is not discussed.

Stroebel and Glueck allege that patients with autonomic hyperactivity lost most of their anxiety symptoms during an eight-week course of twice-daily meditation. The authors suggest that specific psychosomatic symptoms may respond better to biofeedback than to meditation. A striking finding is the poor compliance by psychiatric inpatients with Wolpe/Jacobson or Benson relaxation training compared with the good compliance accorded meditation. The latter apparently was less tiresome to the subjects. Stroebel and Glueck's enthusiastic claims, however, are not in tune with the three related chapters in this book.

Widespread research interest was kindled by early biofeedback reports from Miller and DiCara, who studied operant conditioning of autonomic responses of curarized animals, and Kamiya, who studied voluntary enhancement of alpha brainwaves and consequently of pleasant relaxation. A decade's work has brought forth a considerable body of data and some promising therapeutic applications. Ironically, however, the original studies have been seriously questioned. Roberts' chapter in the present volume ruefully concludes that "the phenomena reported in these experiments are unlikely to have been a product of learning. . . . The power of operant conditioning as a technique for treating visceral pathology appears to have been overstated in the past."

Orne and Wilson demolish essentially all of the popular claims about alpha biofeedback training for the achievement of health or bliss: "Once novelty and visuomotor effects are eliminated, alpha augmentation may be the product of relaxation in one individual and of hyperarousal in another, while a third may show little relationship between subjective state and alpha density." Orne's exciting talent for always asking yet another discerning question is fully evident in this chapter, a masterpiece of research detective work.

Lynch and Schuri reply to the question, Can individuals learn to modify the automatic regulation of the peripheral vascular system? Their answer: yes, sometimes, to some extent, and especially if the subjects are children; but not by means of biofeedback or direct conditioning. Classical conditioning may alter peripheral vascular response indirectly through the agency of an antecedent "central" reaction. Other influences could be focal isometric exercise, subject/experimenter interaction, and certain cognitions.

Ádám, one of the book's two eminent contributors from behind the Iron Curtain, gives new meaning to "making the unconscious conscious." Human subjects stimulated in the duodenum or on the cervix uteri showed EEG changes but felt nothing at a certain voltage. As verbal feedback was provided, the subjects began to perceive the visceral stimuli more and more readily. One wonders if this work could have clinical application in such problems as enuresis, encopresis, and anorgasmia.

Luria, the Soviet scientist to whom this volume is posthumously dedicated, provides a broad neuropsychological review and update. He depicts human consciousness as a brain network coordinated by language and continuously developing in response to life experiences. This conception of consciousness renders untenable birth trauma, primal scream theories, and the literal interpretation of such phenomena as hypnotic age regression and multiple personality.

Finally, the chapter by McGuigan succeeds in establishing that nonoral motor responses are regularly associated with speech and thought. Whether these motor responses are fundamental or even important to speech and thought is something else again.

Most psychiatrist readers would welcome more help from the editors. In future volumes Schwartz and Shapiro might consider attempting an integration or at least an explanation of conflicting viewpoints.

JOSEPH S. SILVERMAN, M.D.
Altoona, Pa.

Family Therapy in Clinical Practice, *by Murray Bowen, M.D. New York, N.Y., Jason Aronson, 1978, 547 pp., $25.00.*

Murray Bowen, one of the foremost pioneers in family therapy, has significantly increased the therapist's theoretical and clinical range. Because for him psychoanalysis and current practice were not resting places but stepping stones to general systems theory, the meaning and scope of the therapist's involvement have been greatly extended. As a consequence, this book, a collection of Bowen's most important papers published since 1957 representing the evolution of his family systems theory, will be of serious interest to all mental health professionals.

Bowen was not content with the opportunities for brilliant intuitions and philosophical operations that are so often the delight and comfort of the therapist's task. Nor would he accept the givens of his time as a place to start. His work demonstrates an original thinker's slow, methodical accumulation of data in clinical practice, research, and teaching, hewing as close to a scientific model as possible. Observations of results led to such changes as seemed useful. This is the essence of modern "operation control."

For example, the hospitalization of the family of a schizophrenic patient as well as the patient in a research study conducted during 1954–1959 at the National Institute of Mental Health led to clear and amazing observations about the relationship of the "patient's" behavior to what happened in the family and the hospital staff. Heretofore unavailable data and modifications became available for testing. The results were a family concept of schizophrenia, the development of a method of family therapy, and extension of the family relationship patterns seen in schizophrenia to families with less severe forms of emotional illness.

A serendipitous control study became available before Bowen actually realized it was such. In 1967 he discovered that psychiatric residents he saw only once a month informally, who were encouraged to visit their relatives and establish a person-to-person relationship but not get drawn in-

to their emotional system, made greater progress in working out problems in their nuclear families than residents he saw weekly in formal family therapy with their spouses. This discovery was a turning point in Bowen's professional development. The implications of this finding, if further validated, offer hope for mental health and preventive medicine in a society in which the progress of technology has tended to separate families and weaken roots.

One semantic consideration and a caveat should be mentioned. Labeling is often a problem in new work. Combinations of three relationship names, e.g., "father-mother-child," can denote the interface of many different systems configurations. When such a "triangle" is discussed, a modifier is needed to make clear that the three people do not relate in only one way. For example, one could speak of progressive triangles or regressive triangles. The caveat has to do with Bowen's discounting of group therapy. As often happens when a very experienced practitioner of one method regards unfavorably another method with which he or she has less experience, Bowen fails to recognize the applicability of group therapy to family systems. He makes the point that he does family therapy with one person but then inconsistently refers to the therapy group as a "number of individuals" rather than regarding it more fittingly as a "number of family representatives." In so doing, he eliminates the possibility of helping his "low-scale" families (low on the differentiation-of-self spectrum) to whom he offers so little hope. In such cases, when the resources of one therapist may be overwhelmed, a therapy group or a multiple therapist team (e.g., Whittaker and associates) offers the input of several family systems. This is not only a quantitative but a qualitative addition.

This criticism does not take away from the magnitude of Bowen's contribution. In my opinion, not every practitioner has the therapeutic personality to use Bowen's method successfully. To remain "detriangled" in the therapeutic system, special training is usually necessary, as well as the actual experience of differentiating from one's own family. However, the mental hygienic possibilities as Bowen's method becomes part of the culture (as Freud's work has) are very great. It could be a revolutionary contribution.

DAVID MENDELL, M.D.
Houston, Tex.

The Language of Change: Elements of Therapeutic Communication, *by Paul Watzlawick. New York, N.Y., Basic Books, 1978, 166 pp., $11.00.*

Dr. Watzlawick promises a challenging and innovative discussion of the use of language in psychotherapy. He attempts to synthesize research data on brain lateralization and to present an approach to the use of this information for the psychotherapist. Unfortunately, the promise is not fulfilled.

Throughout the book there is an intermingling of philosophical concepts and literary references to add emphasis and make distinctions in areas that are less clear than the author proposes. Watzlawick draws sharp distinctions between right and left brain functioning on the basis of recent as well as classical studies. Although research in the last decade has produced considerable support for the lateralization of brain functioning, clinical implications are as yet far from accurately charted. Right and left brain differences clearly exist, but it appears that in intact humans sharp divisions are not as well-defined as the author proposes. Integrated functioning and synthesis occurs, but special emphasis is evident in data on asymmetric activation in normal individuals, handedness, and sex differences in brain organization. Preliminary data also suggest the possibility of lateralization in schizophrenia and affective disorders. However, this is not clearly established, nor are the implications understood.

The author's purpose in providing evidence for the separation of right and left hemisphere functions is to explore the implications for therapy. He proposes a language that "blocks the left hemisphere" and "speaks" to the right. In this endeavor he uses clinical material largely drawn from the work of Dr. Milton Erikson, which does not provide a definitive model. The examples range between those which are useful and interesting to those which lack sophistication and depth and are at times manipulative and disrespectful to patients. In any event, they are not astonishing revelations. Watzlawick often sets up straw men to topple. He does not consider newer developments in theory and technique, including those from psychoanalysis and behavior modification. The value of the text resides in its rich store of literary examples and some interesting clinical material, but it is hardly the unique and revolutionary approach promised at the outset.

CAROL C. NADELSON, M.D.
Boston, Mass.

The Private Worlds of Dying Children, *by Myra Bluebond-Langner. Princeton, N.J., Princeton University Press, 1978, 275 pp., $12.50.*

The social scientist can make important contributions to pediatric oncological care. Bluebond-Langner does that in her anthropological study of the child's view of a pediatric hospital oncology ward and clinic. To present the child's view is always refreshing and, even if the children are dying of leukemia, their ways of adapting to, denying, subverting, ignoring the hospital's social structure, and otherwise trying to maintain their real values in the face of death are so authentic that they give zest and dignity to a world that is catastrophic for the children and their families. The author's device of a play to convey the drama of a child's world is a sparkling beginning for the book.

The perspective of the social scientist allows the author both an armor and a vulnerability that a "real" member of the health team would never know. Bluebond-Langner's vulnerability comes from the fact that she was not a member of a "helping profession" in this hospital setting. She was not there to help but to learn, understand, and to do no harm. In fact, she says that the clinical workers showed unvarnished hostility toward her when one patient relapsed. At times, she seemed to be in the way, at times too peripheral, but she succeeded in observing 32 patients between ages 3 and 9 years. The things she found out can only aid the humane clinical worker.

The armor protecting the author could be envied by pediatricians, one suspects: she had the freedom to move forward only when she had the fully informed consent of the child. Indeed, she did not intrude when the child did not welcome her; she could leave as soon as a parent came to be with the child. At all other times, however, she was an empathetic presence, remaining long hours with the children to provide companionship and understanding. To be able to talk with children under a contract that one will not be intrusive would

be a desirable Utopia for clinicians on a leukemia ward. The author's implicit message is that if clinicians desired it, they could take on more of the noninterventive outlook of the anthropologist. I agree; children respond honestly to honest inquiry about their private worlds. Even dying children are responsive:

> I will act as an observer. I will talk with the child only when he speaks with me. At no time will I introduce the subject of his illness, or ask questions about his condition. I am interested in what is on the child's mind and what he chooses to express. I am interested in his means of communication and how he chooses to use them with regard to the variety of plans and purposes a child has. (p. 49)

The preceding quotation might have been taken from an informal statement by Jean Piaget or David M. Levy, but Bluebond-Langner gives no sign that she has experienced the slightest breeze from Piaget on the matter of a child's self-concept or problem-solving skills. Piaget would have made very apt background reading and would have altered and added credibility to some of Bluebond-Langner's generalizations. Her generalizations of what the child knows are skewed in favor of the cognition of a 9-year-old. That bias—almost a fatal blunder—pervades chapters three through seven. Therefore, what is supposed to be original is sometimes based on unfamiliarity with other scientists who have reported their work with children in the non-social sciences literature.

Whenever adults undertake to colonize the head of a child, they portray the child as a budding young criminal living according to a pleasure principle; at the same time the adults curb the child from obtaining gratifications until he or she is older. "Later" is a strong word for adults who socialize children. The child must wait, taking on a perspective of preparing for pleasures later on. The leukemic children presented in this book have no future pleasures. They know it, and they try to make do. One closes this interesting, tender book with a wish that the adults could do their jobs as well as the children do their dying.

PAUL L. ADAMS, M.D.

Minimal Brain Dysfunction: Fact or Fiction. Advances in Biological Psychiatry, Vol. 1, *edited by A.F. Kalverboer, H.M. van Praag, and J. Mendlewicz. Basel, Switzerland, S. Karger, 1978, 107 pp., $25.50 (paper).*

A review of a book of collected papers follows a fairly well agreed on format. The reviewer notes that the papers are of mixed quality, making any generalization difficult. No reviewer has—to the best of my knowledge—applied what might be called the "medical rule of thirds." As we all remember, a handy mnemonic for most treatments is that one-third of the patients improve, one-third get worse, and one-third remain the same. By analogy, one-third of the articles in collected volumes generally seem to be enlightening, one-third uninspired, and one-third toxic to the reader's intellectual organization.

The novice who wishes to learn something about minimal brain dysfunction need not read this book because a number of broader summaries are available elsewhere. To those of us obsessives who like to keep up this review produces a sigh of relief because it is one book in the torrent that need not be read. The significance of this book is that, finally, our European colleagues have taken notice of the fact that minimal brain dysfunction, which has been the object of so much attention in American child psychiatry, *may* be a "real" syndrome. This is an advance, illustrated by an epidemiological study conducted by the productive and creative English psychiatrist Michael Rutter, who found one hyperactive child on the Isle of Wight.

A number of the contributors to this book feel uncomfortable with a minimal brain dysfunction syndrome because patients given this diagnosis need not have identical characteristics. This is hardly unique to minimal brain dysfunction; it is characteristic of other syndromes accepted on the Continent, such as the schizophrenias and affective disorders. There are a few other interesting errors in logic, such as the idea that the use of one name implies a unitary etiology. Otherwise, the issues discussed in the book are no longer discussed in American academic circles; these include the relationship between demonstrable brain damage and behavioral deviations and the relationship between neurological findings and behavioral difficulties. The paper of most interest is that by Grahame-Smith, who succinctly reviews the current animal models for the syndrome.

The fact that this book has appeared in Europe is indicative of a narrowing of the child psychiatric cultural lag that has existed between the United States and Western Europe. To those of us who believe that in minimal brain dysfunction we are dealing with a phenomenologically distinct and important syndrome characterizing many disturbed children and some adults, this cannot but be welcome. As behaviorists have observed, even critical attention is more positively reinforcing than complete neglect. Less cynically, I hope this book signifies that some of our colleagues in Western Europe are beginning to consider and deal with this important and common, if misnamed, syndrome.

OFFICIAL ACTIONS

1979 Annual Meeting: Registration and Related Information

The 132nd annual meeting of the American Psychiatric Association will be held in Chicago, Ill., May 12–18, 1979; the theme of this meeting is "The Scientific and Humanistic Future of Psychiatry." The information here is what was available as of mid-January 1979. The official program book containing the scientific, business, and social program will be distributed in Chicago at the time of registration. (The preliminary scientific program is printed in the March 2 issue of Psychiatric News.)

REGISTRATION

All registration will take place in the Conrad Hilton Hotel. The registration desk will be open:

Saturday, May 12—1 p.m. to 5 p.m.
Sunday through Thursday, May 13–17—8 a.m. to 5 p.m.
Friday, May 18—8 a.m. to 10 a.m.

A registration fee of $15 per day, or $60 for all seven days, is required from all nonmembers with the exception of 1) invited nonmember program participants and their immediate families, 2) APA members and their immediate family members living in the same household. Associate members, members-in-training, and their immediate family members living in the same household, and 3) foreign visitors outside of the U.S. and Canada. The fee covers admission to the sessions and includes a badge and a copy of the official program. Badges are required for all sessions (including the opening session) and for the exhibit area. However, a badge does not cover admission to the business session of the Association, which is open only to voting members.

A $20 registration fee is required of military personnel on active duty.

A $10 registration fee is required of the spouses and dependents of all nonmember registrants (excluding invited nonmember program participants).

A $15 registration fee is required of medical students, interns, residents, chaplains, nursing students, and students in the mental health professions. Students must present a letter from their school or training facility instructor certifying their status.

The *Scientific Proceedings in Summary Form* for the 1979 annual meeting will be available throughout the week in the Conrad Hilton Hotel.

KEY LOCATIONS

All APA staff offices will be located on the fifth floor of the Conrad Hilton Hotel:

Administrative Office	Rooms 418, 419
Meetings Management	Continental Room, Main Lobby
Program Committee	Room 415
Journal Office	Room 412
Press Offices	Rooms 413, 414
Local Arrangements and Spouse Hospitality Center	Normandie Lounge
Registration	North Hall, Lower Level
Information and Message Center	Lower Level Lobby
Membership Resource Center	East Hall, Lower Level

INFORMATION AND MESSAGE CENTER

This center will be located in the Conrad Hilton Hotel and will be manned during registration hours. Self-service message racks will be available for pick-up, deposit, and exchange of messages at all times, even when the message center is closed. Extremely urgent messages will receive the personal attention of APA staff members. All registrants are requested to check the message center periodically. There will also be satellite information centers in the Marriott, Palmer House, and Hyatt Regency Hotels.

JOURNAL OFFICE

The office of the *American Journal of Psychiatry* will be in Room 412 of the Conrad Hilton Hotel. The office will be open from 8:00 a.m. to 5:00 p.m., Monday through Thursday, and on Friday until 12:00 noon. Staff will be available to discuss any questions that authors who are presenting papers at the meeting may have. They particularly welcome the opportunity to confer with authors about tables and figures to be included in the papers.

The *Journal* has first refusal rights for all numbered papers. Permission must be secured from the Editor, John C. Nemiah, M.D., before a paper may be submitted elsewhere. The *Journal* will accept for review only papers that are in final form and conform to the requirements listed in "Information for Contributors." The *Journal* does not hold first refusal rights for new research papers and papers presented at morning workshops and evening panels; however, authors may submit them for publication if they wish.

It is the policy of the *Journal* to publish only original material that has not been published elsewhere in any form and that is not being considered for publication elsewhere.

CONVOCATION

The convocation will take place Monday, May 14, at 7:30 p.m. in the International Ballroom of the Conrad Hilton Hotel. The William C. Menninger Memorial Lecture will be given at the convocation by Dr. Robert Jastrow.

SPOUSE HOSPITALITY CENTER

The Local Arrangements Committee will host a Spouse Hospitality Lounge in the Normandie Lounge of the Conrad Hilton Hotel. Information on all leisure-time activities will be available Sunday through Friday in this area. All tours will depart from the 8th Street entrance of the Conrad Hilton Hotel.

PLACEMENT SERVICE

There will be a register available in the Membership Resource Center for prospective employers and for those seeking positions.

SHUTTLE BUS SERVICE

Bus service will be available among the hotels. Route maps, hours of operation, and fare information will be available at the Information and Message Center.

ARTS AND CULTURE

A special performance of the award-winning musical "Annie" will be presented at the Arie Crown Theater on Tuesday, May 15, at 8:00 p.m. Complimentary reserved tickets will be available for APA members (2 per registrant) at a special ticket booth on a first-come first-serve basis. Complimentary shuttle bus service will be provided to and from the theater. A symposium on "Annie" will be held on Wednesday, May 16, from 2:00 p.m. to 5:00 p.m. in the Red Lacquer Room of the Palmer House.

CONTINUING EDUCATION CREDIT

The official annual meeting program, with a few exceptions, meets the criteria for continuing medical education Category I credit. One hour of credit may be claimed for each hour of participation. As an organization accredited for continuing medical education activities, the American Psychiatric Association certifies that the continuing medical education activities designated Category I meet the criteria for Category I for the Physician's Recognition Award of the American Medical Association on an hour-for-hour basis. Continuing medical education sessions are open to all meeting registrants. Check the tentative program schedule in the February 2 issue of *Psychiatric News* for sessions that offer Category II credit.

All program activities are designated either Category I or Category II; these include courses, symposia, paper sessions, special lectures, video, films, panels, and issue workshops. Seven two-day courses on Saturday, May 12, and Sunday, May 13, and five symposia on Sunday, May 13, may also be taken for additional Category I credit. Half-day courses on Tuesday and Friday will be held from 10:15 a.m. to 2:15 p.m. and on Monday from 2:00 p.m. to 6:00 p.m. Full-day courses will be offered on Wednesday and Thursday from 10:15 a.m. to 5:15 p.m.; one full-day course on Wednesday will be offered from 10:15 a.m. to 6:15 p.m. All full-day courses have a 1-hour break for lunch. Preregistration coupons for courses (March 23 deadline) and complete course descriptions can be found in various January-February-March issues of *Psychiatric News*.

MORNING WORKSHOPS AND EVENING PANELS

Issue workshops will be held on Tuesday, Wednesday, and Thursday from 10:30 a.m. to 12:00 noon. All issue workshops offer Category II credit with the exception of those starred in the official program, which offer Category I credit. Evening panels will be held on Tuesday, Wednesday, and Thursday from 8:00 p.m. to 10:00 p.m. All evening panels offer Category I credit. All workshops and panels will be held at various hotels.

VIDEOTAPE PROGRAM

Videotape sessions will be shown on wide-screen closed-circuit color TV in the Conrad Hilton, Grand Ballroom, 2nd floor, from 2:00 p.m. to 5:00 p.m. on Monday, Wednesday, and Thursday, and from 8:00 a.m. to 9:45 a.m. on Tuesday and Friday.

FILMS

All films will be shown in the Palmer House, State Ballroom, 4th floor. Noon film features can be seen Monday through Friday and evening film features can be seen Tuesday and Wednesday at 8:00 p.m.

SPECIAL LECTURES

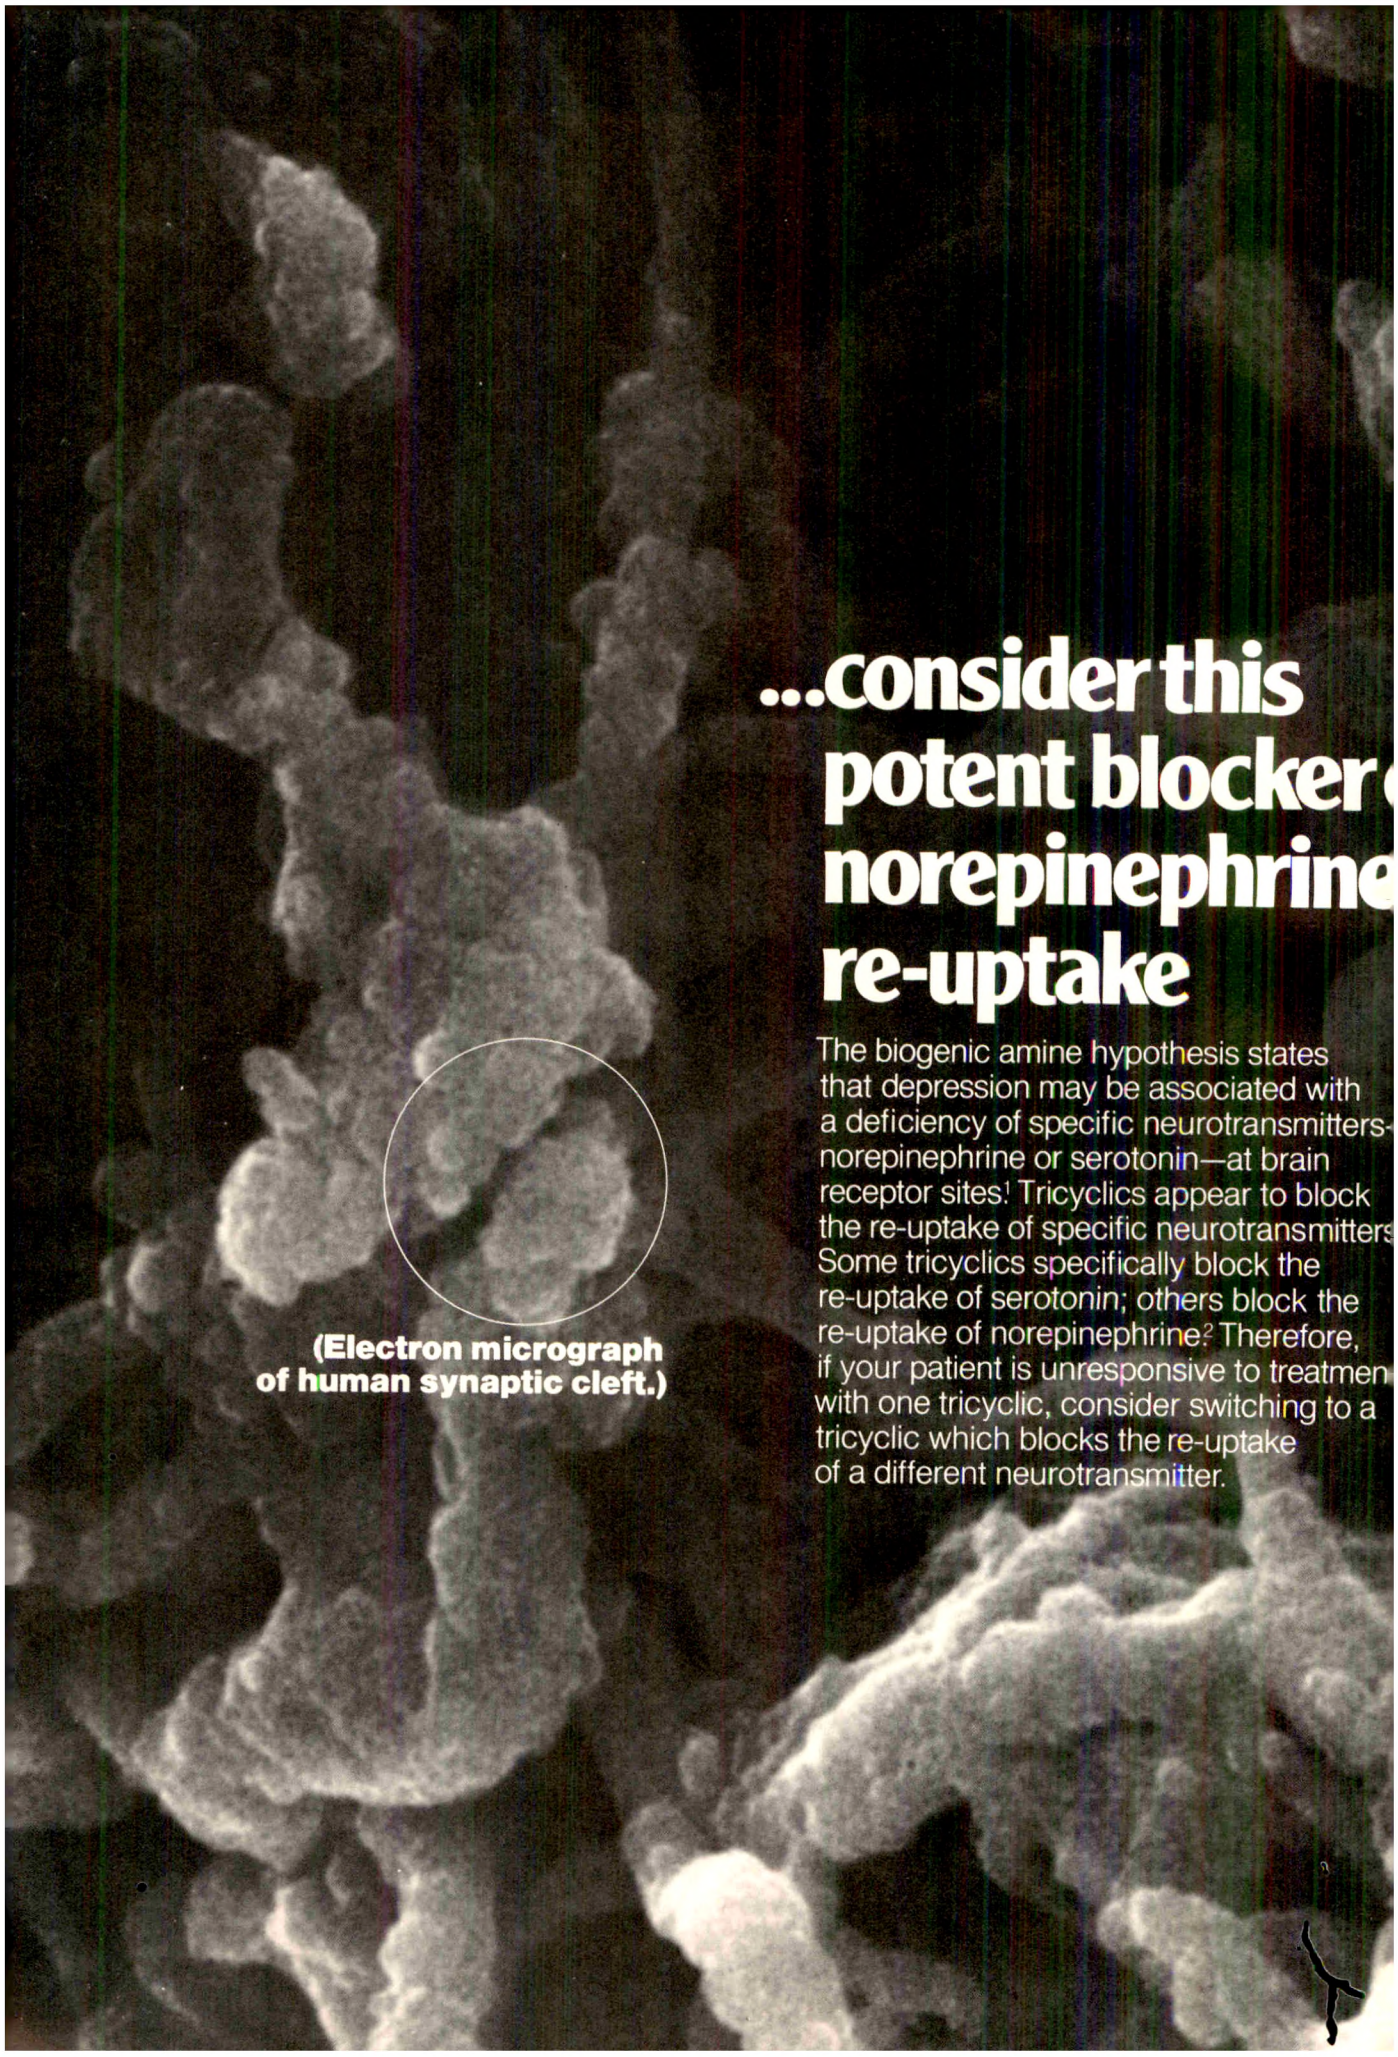
APA will sponsor 30 special lectures this year. Among the named lectures will be the Adolf Meyer Lecture (Tuesday, 1:30 p.m. to 3:00 p.m.), the Benjamin Rush Lecture (Wednesday, 10:30 a.m. to 12:00 noon), the Manfred S. Guttmacher Lecture (Wednesday, 10:30 a.m. to 12:00 noon), the Solomon Carter Fuller Lecture (Wednesday, 2:00 p.m. to 3:30 p.m.), the Seymour Vestermark Lecture (Wednesday, 3:45 p.m. to 5:00 p.m.), the Simon Bolivar Lecture (Thursday, 10:30 a.m. to 12:00 noon), and the APA Founders Award Lecture (Thursday, 10:30 to 12:00 noon). Among the guest lecturers will be the Reverend Jesse L. Jackson (Monday, 2:00 p.m. to 5:00 p.m.), Professor Archibald Cox (Monday, 3:45 p.m. to 5:00 p.m.), Congressman Paul Rogers of Florida (Tuesday, 10:30 a.m. to 12:00 noon). Included in the 30 lectures will be an APA Lecture Series, featuring 13 distinguished psychiatrists and nonpsychiatrist physicians.

NEW RESEARCH

These sessions will be held on Tuesday through Friday from 8:00 a.m. to 9:45 a.m. in the Hyatt Regency, Ballrooms A, B, and C. All 12 sessions will offer Category II credit. Program leaflets containing all details will be available at the registration desk.

EXHIBITS

Scientific and technical exhibits will be on display in the Conrad Hilton Hotel Monday through Wednesday, 9:00 a.m. to 4:30 p.m., and Thursday, 9 a.m. to 2 p.m.



LUNCHEON IN HONOR OF FAMILIES OF APA OFFICERS

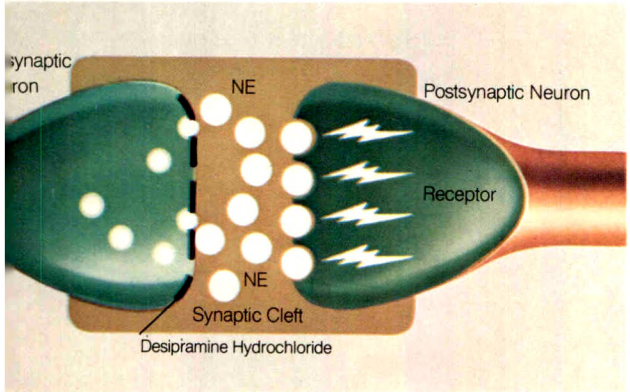
A luncheon will be held in honor of the families of APA officers on Tuesday, May 15, from 11:30 a.m. to 1:30 p.m. at the Chicago Public Library and Cultural Center. Tickets for the luncheon are $10 per person and may be purchased at the Leisure Time Activities Ticket Sales Desk.

APA DINNER DANCE

A dinner dance featuring two bands, one before and on during dinner, will be held on Wednesday, May 16, at 7:3 p.m. in the Grand Ballroom of the Conrad Hilton Hote Tickets are $25 per couple and may be purchased at the Le sure Time Activities Ticket Sales Desk or in advance throug a leisure time activities coupon published in a brochur mailed to each member.

When your patient is clinically depressed...
"...everything I saw was negative."

...consider this potent blocker of norepinephrine re-uptake



The biogenic amine hypothesis states that depression may be associated with a deficiency of specific neurotransmitters-norepinephrine or serotonin—at brain receptor sites[1] Tricyclics appear to block the re-uptake of specific neurotransmitters. Some tricyclics specifically block the re-uptake of serotonin; others block the re-uptake of norepinephrine.[2] Therefore, if your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic which blocks the re-uptake of a different neurotransmitter.

(Electron micrograph of human synaptic cleft.)

Norpramin®
desipramine hydrochloride (tablets NF)
5, 50, 75, 100, 150 mg.

tent blocker norepinephrine re-uptake

cording to current theory[1,3] some yclic antidepressants may fail in certain es of depression because they are not ficiently potent blockers of norepi- hrine re-uptake. Laboratory studies ve shown that desipramine is the most ent inhibitor of norepinephrine uptake.[4] Norpramin may work in some ents when other tricyclic antidepres- ts do not.

onsider it now, onsider it next.

Less anticholinergic activity

(See Warnings section.)

Studies in animals[5] and in normal human subjects[6,7] have shown that desipramine has significantly less anticholinergic activity than amitriptyline or doxepin. The single bond side chain is associated with lower anticholinergic activity than these other leading antidepressants. This may mean:

- less dry mouth
- less blurred vision
- less urinary retention

Helps patients remain calm but active

Norpramin does not usually inhibit normal activity although patients should be cautioned as to driving or operating machinery if drowsiness occurs.

In addition...

Begins to improve sleep patterns within one week in some patients[8]

- Norpramin helps relieve the sleep disturbances that often accompany depression.
- As the depression is relieved, the difficulty in falling asleep, restlessness, and early morning awakening diminish.

Merrell

Now 300 mg. dosage range broadens clinical flexibility

A maximum dosage of 300 mg. a day, as a single or divided dose, may now be prescribe Norpramin. Since inadequate dosage is thought to be one of the major causes of treatme failure, the new therapeutic range should prove clinically helpful. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Norpramin®
(desipramine hydrochloride tablets NF)

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: 1. Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. **2.** This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. **3.** USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. **4.** USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. **5.** The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. **6.** In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: 1. It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. **2.** If serious adverse effects occur, dosage should be reduced or treatment should be altered. **3.** Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. **4.** The drug may cause exacerbation of psychosis in schizophrenic patients. **5.** Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. **6.** Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. **7.** Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. **8.** The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. **9.** This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. **10.** Both elevation and lowering of blood sugar levels have been reported. **11.** Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

ADVERSE REACTIONS: Note: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enla ment and galactorrhea in the female; increased decreased libido, impotence, testicular swelling; el tion or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered l function; weight gain or loss; perspiration, flush urinary frequency, nocturia; parotid swelling; dro ness, dizziness, weakness and fatigue, headache; pecia.

Withdrawal Symptoms: Though not indicative of ad tion, abrupt cessation of treatment after prolor therapy may produce nausea, headache, and mala

DOSAGE AND ADMINISTRATION: Not recommended for in children. Lower dosages are recommended for elc patients and adolescents. Lower dosages are recommended for outpatients compared to hospital patients, who are closely supervised. Dosage shoul initiated at a low level and increased accordin clinical response and any evidence of intolera Following remission, maintenance medication ma required for a period of time and should be at the lo dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 20 per day. In more severely ill patients, dosage ma further increased gradually to 300 mg./day if neces Dosages above 300 mg./day are not recommended

Dosage should be initiated at a lower level increased according to tolerance and clinical resp

Treatment of patients requiring as much as 300 should generally be initiated in hospitals, where re visits by the physician, skilled nursing care, and quent electrocardiograms (ECG's) are available.

The best available evidence of impending to from very high doses of Norpramin is prolongation QRS or QT intervals on the ECG. Prolongation of th interval is also significant, but less closely corre with plasma levels. Clinical symptoms of intolera especially drowsiness, dizziness, and postural hyp sion, should also alert the physician to the nee reduction in dosage. Plasma desipramine measure would constitute the optimal guide to dosage mo ing.

Initial therapy may be administered in divided or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescen geriatric dose is 25 to 100 mg. daily.

Dosage should be initiated at a lower leve increased according to tolerance and clinical resp to a usual maximum of 100 mg. daily. In more sever patients, dosage may be further increased to 150 day. Doses above 150 mg./day are not recommend these age groups.

Initial therapy may be administered in divided or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a di sion of symptoms and treatment of overdose.

decreased by 1/3 or
from baseline.

Greater patient improvement

Within the first week—

twice as many patients achieved significant relief—sooner than with amitriptyline alone

omnia, a major target symptom, can
relieved sooner by taking advantage
he sedative effect of Limbitrol. For
he patients, the larger part or all of
daily dose may be given at bedtime.

Better relief of symptoms

Within the first week—

symptom severity was reduced to a greater extent than with amitriptyline alone

As measured by the Hamilton Depression Scale

- insomnia
- psychic anxiety
- somatic anxiety
- agitation
- suicidal ideation
- worthlessness

As measured by the Beck Depression Inventory

- pessimism
- dissatisfaction
- guilt
- social withdrawal
- anorexia

imbitrol®

ets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

ets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)

rapid relief of
derate to severe
pression and anxiety

Greater patient acceptance

- Despite a higher incidence of drowsiness, there was a lower dropout rate due to side effects with Limbitrol than with amitriptyline

(Limbitrol 4%, amitriptyline 13%, chlordiazepoxide 1%)

- The dropout rate due to therapeutic failure was lower with Limbitrol than with amitriptyline

(Limbitrol 2%, amitriptyline 6%, chlordiazepoxide 12%)

ROCHE

How to Initiate and Maintain Therapy

Select dosage strength appropriate for each patient

- Limbitrol 10-25 is recommended for most patients
- Limbitrol 5-12.5 may be indicated for those who do not tolerate higher doses and for elderly patients

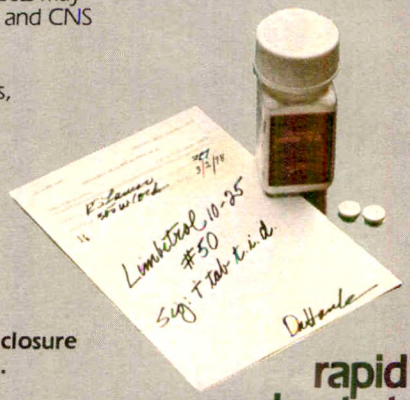
Specify daily dosage based on symptom severity

- An initial dosage of three tablets is recommended
- Dosage may be increased to six tablets or decreased to two tablets daily as necessary
- Once a satisfactory response is obtained, evaluate response, and if necessary, reduce dosage to smallest amount needed to maintain remission

Utilize dosage options to best accommodate individual patient needs

- T.I.D. or Q.I.D., familiar regimens best suited for patients who tolerate medication without undue drowsiness
- Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
- Entire dosage h.s. to take maximum advantage of the sedative effect

How to make each patient an informed patient



1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted or the symptom treated.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under t following circumstances

1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Should not be given with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for minimum of 14 days before cautiously ini ing Limbitrol therapy.
3. During the acute recovery phase follo ing myocardial infarction.

Limbitro

F
rapid relief
moderate to seve
depression and anxie

LIMBITROL® TABLETS
Tranquilizer–Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated; sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs.
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergics: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urin tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression includin agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomasti the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaund alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatm symptomatic and supportive. I.V. administration to 3 mg physostigmine salicylate has been repo to reverse the symptoms of amitriptyline poisoni See complete product information for manifesta and treatment.
Dosage: Individualize according to symptom se and patient response. Reduce to smallest effec dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at be Single h.s. dose may suffice for some patients. dosages are recommended for the elderly.
Limbitrol 10-25, initial dosage of three to four tab daily in divided doses, increased up to six table decreased to two tablets daily as required. Limb 5-12.5, initial dosage of three to four tablets dail divided doses, for patients who do not tolerate doses.
Supplied: Limbitrol 10-25 tablets each contain mg chlordiazepoxide and 25 mg amitriptyline (a hydrochloride salt) and Limbitrol 5-12.5 tablets containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottle 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 50.

Announcing a Special Issue of **The American Journal of Psychiatry** *on*

DEPRESSION and ALCOHOLISM

This mid-April special issue, included in regular subscriptions to the *American Journal of Psychiatry*, focuses on two topics of intense concern to the psychiatric profession: depression and alcoholism.

Containing 30 original articles, it covers the spectrum of diagnostic considerations, treatment, management and complications, etiology and phenomenology. The emphasis throughout is clinical. While several articles explore new work on alcoholism and on the relationship between depression and alcoholism, current studies on depression dominate this valuable collection.

Partial List of Topics

Diagnosis

Depression simulating organic brain disease — diagnosis and lithium treatment of manic-depressive disorder in the retarded — delineation of an MMPI symptom pattern unique to lithium responders

Treatment, Management

Depression treated with imipramine and ECT — possible cardiovascular effect of lithium — lithium maintenance: factors affecting outcome — efficacy of drugs and psychotherapy in the treatment of acute depressive episodes

Etiology, Phenomenology

Life events at the onset of bipolar affective illness — childhood depression: interpersonal interactions and depressive phenomena — drug abuse among alcoholic women — psychiatric problems in women during alcoholic detoxification — life events, coping, stress, and depressive symptomatology

A special Guest Editorial by Morris A. Lipton, Ph.D., M.D., provides a unifying perspective to this special issue.

Extra copies of the April 1979 Special Issue (the 2nd April issue) will be available at $2.25 (domestic), $2.90 (foreign). *Payment must be included with order.* Order from:

American Psychiatric Association, Circulation Department, 1700 18th Street, NW, Washington, DC 20009

Must the MBD child take a controlled drug in school?

Not if he's taking Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets

Children can be cruel. Their teasing about taking noontime medication can cause serious problems for the child with MBD.

Here's how Cylert eliminates this problem:

- Once a day dosage at home
- Eliminates mid-day school dose

In addition, Cylert offers these benefits:

- Avoids ups and downs of drug action brought about by multiple daily dosage
- Control of medication by the parent
- A chewable dosage form
- Less physician paper work (Cylert is in schedule IV)
- Safety and efficacy proven in extensive clinical studies*

*Copy of the Cylert Monograph available to Physicians on written request.

When not to use medication

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school-age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

8083261 R

Please see next page for Prescribing Information.

Cylert and Cylert Chewable Tablets

(pemoline)

Prescribing Information

Indications: *MINIMAL BRAIN DYSFUNCTION IN CHILDREN*—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: The cause of minimal brain dysfunction (MBD) is unknown. Diagnosis of MBD involves the use of medical, psychological, educational, and social tools, since no single diagnostic test is adequate.

MBD is characterized by chronic moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindications: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

Warnings: Cylert is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Sufficient data on the safety and the efficacy of the long-term use of Cylert in children with minimal brain dysfunction are not yet available.

A temporary suppression of the predicted growth rate (weight and/or height gain) has been reported for children receiving long-term stimulant therapy. A definite causal relationship between stimulant drugs and this finding has not been established.

Precautions: Liver function tests should be performed periodically during therapy with Cylert. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

Cylert should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of Cylert with other drugs has not been studied in humans. Patients who are receiving Cylert concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

Cylert failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with Cylert. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. Cylert should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of Cylert (pemoline) for use during pregnancy and lactation has not been established.

Fertility, reproduction, and teratology studies were conducted in laboratory animals. Pemoline, in doses of 18.75 or 37.5 mg./kg./day, had no effect on the fertility of male or female rats. The drug, when given to pregnant rats (from gestation day 15 through weaning) and to rabbits (from gestation days 6-18) at these same dosage levels, produced no teratogenic or embryotoxic effects, and had no effect on the viability of the young at birth. However, increased incidences of stillbirths and cannibalization were observed when pemoline was given to rats at these dosage levels, beginning 14 days prior to conception.

Adverse Reactions: Insomnia is the most frequently reported side effect of Cylert; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking Cylert, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking Cylert; a causal relationship between the drug and this clinical finding has not been established.

There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert. Convulsive seizures have also been reported. A definite causal relationship between Cylert and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with Cylert often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (white) in bottles of 100 (**NDC** 0074-6025-13)
37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)
75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

Cylert Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored)
in bottles of 100 (**NDC** 0074-6088-13)

CHARLES C THOMAS · PUBLISHER

VALUES CLARIFICATION FOR COUNSELORS: How Counselors, Social Workers, Psychologists, and Other Human Service Workers Can Use Available Techniques *by* **Gordon M. Hart,** *Temple Univ., Philadelphia, Pennsylvania.* The opening chapter of this text introduces the general nature of values and explains how people can be assisted in examining their own values and behavior. It also discusses theoretical positions and practical applications of the values clarification technique. The remainder of the text details preparation for and utilization of the prizing, choosing and acting stages of the clarification process. The author also gives guidelines for selecting, sequencing and conducting discussions following the application of this procedure. *'79, 104 pp., 4 il., $9.00*

FAMILY THERAPY AND EVALUATION THROUGH ART *by* **Hanna Yaxa Kwiatkowska,** *The George Washington Univ., Washington, D. C. Foreword by* **Lyman C. Wynne.** This book describes the special kind of communication provided by the graphic and plastic media, and how it can and is being used with families for therapy, evaluation and research. Details of the family art session are presented, followed by discussions of family art therapy as it relates to adjunctive verbal therapy and to hysterical and schizophrenic patients. The procedures of family art evaluation are then meticulously examined. *'78, 304 pp., 125 il. (12 in color), 7 tables, $21.75*

THE PSYCHOLOGY OF LEISURE: Research Approaches to the Study of Leisure (3rd Ptg.) *by* **John Neulinger,** *City College of The City Univ. of New York, New York City.* The goal of this book is to redefine the concept of leisure and to make it the ultimate goal of society. Eight areas of possible research are outlined. These include the conceptualization of leisure, measurement of leisure, collection of leisure facts, leisure in the social-psychological context, formation of leisure attitudes, experimental leisure research, and the promotion of leisure. The concept that leisure is a state of mind is stressed. *'78, 240 pp., 1 il., 14 tables, $12.25*

BOMBERS AND FIRESETTERS *by* **John M. Macdonald,** *Univ. of Colorado School of Medicine, Denver. Contributions by* **Robert B. Shaughnessy** *and* **James A. V. Galvin.** Psychologists and related professionals will appreciate the close attention given to the psychological functioning and personality of the bomber and arsonist in this timely book. The author comprehensively explores such topics as bombs and their effects, the motivations of the perpetrators, and victims and targets of these crimes. The urban guerrilla, the bombing campaign in Northern Ireland, a psychiatric study of an airplane bomber, bomb threats and disposal, and the investigation and punishment of these crimes are also discussed. *'77, 264 pp., $15.75*

PSYCHIATRIC DRUGS FOR THE NON-MEDICAL MENTAL HEALTH WORKER *by* **William Goldsmith,** *Brentwood VA Hospital, Los Angeles.* Important data on anatomy, physiology, the biochemistry of psychiatric drugs, and their effects on the patient is presented in this text. The basics of drug usage, including administration, metabolism, mechanisms of action and possible side effects of phenothiazines, antidepressants, lithium, barbiturates and stimulants are all covered in detail. Unnecessary concepts and unfamiliar terminology have been omitted in order to concentrate on those aspects which are crucial to the understanding of the topic. *'77, 188 pp., 27 il., 7 tables, $13.25*

SOCIAL CONFLICT AND MENTAL HEALTH SERVICES *by* **Robert D. Borgman,** *Univ. of Southern Mississippi, Hattiesburg.* The author integrates social conflict theory with phenomenological, developmental, and problem-solving techniques to provide a singularly effective framework for understanding and intervening in the lives of troubled and troublesome individuals and families. Social conflict theory is also related to the problems of mental health organizations and professional relationships. A sampling of other topics includes mental patienthood, suicide and homicide, sexual oppression, school aversion, social conflicts of adolescence, and problems of the elderly. *'79, 356 pp., cloth-$24.50, paper-$18.50*

MANUAL FOR THE ADULT NEUROPSYCHOLOGICAL EVALUATION *by* **Dennis Swiercinsky,** *VA Hospital, Topeka, Kansas.* This is a comprehensive guide to neuropsychological evaluation using a standardized test battery. Detailed instructions for obtaining necessary equipment and for the administration of a standard test battery are provided. Information is also presented on the interpretation of the results and their integration with behavioral, laboratory, social, medical, and neurological data. Preparation of the final clinical report is explained and illustrated with a sample case report. *'78, 208 pp. (6 3/4 x 9 3/4), 19 il., 13 tables, $16.75, spiral (vinyl)*

MICROCOUNSELING: Innovations in Interviewing, Counseling, Psychotherapy and Psychoeducation (2nd Ed.) *by* **Allen E. Ivey,** *Univ. of Massachusetts, Amherst, and* **Jerry Authier,** *Univ. of Nebraska Medical Center, Omaha. Foreword by* **Bernard G. Guerney, Jr.** *(3 Contributors)* The new edition of this book includes updated research on the microcounseling model, chapters on the cross-cultural and cross-racial implications of interviewing training, and material illustrative of how microcounseling skills are used by various types of therapists. A section on operational definitions has also been added. *'78, 624 pp., 13 il., $27.00*

BASIC APPROACHES TO GROUP PSYCHOTHERAPY AND GROUP COUNSELING (2nd Ed., 2nd Ptg.) *edited by* **George M. Gazda,** *Univ. of Georgia, Athens. (20 Contributors)* A convenient reference to basic theories for students and practitioners of group psychotherapy and group counseling is provided. Each chapter follows an outline that enables the reader to compare and contrast each position according to the following aspects: definition, theoretical foundation, related research, treatment goals, group selection and composition, group settings, group size, frequency and duration of sessions, media employed, therapist qualifications, ethical considerations, and limitations of treatment. *'77, 560 pp., 9 il., $19.50*

HYPNOSIS AND BEHAVIOR THERAPY *edited by* **Edward Dengrove.** *(42 Contributors)* Directed toward behavior therapists, hypnotherapists and related specialists, this book will acquaint practitioners of one school with the techniques of the other. Following introductory definitions and descriptions of behavior therapy and hypnosis, a section is devoted to experiments dealing with the effects of hypnosis upon conditionability and other basic phenomena underlying behavior therapy. Following this are discussions of the use of behavior therapy techniques by hypnotherapists and, conversely, the use of hypnosis in behavior therapy. *'76, 428 pp., 30 il., 6 tables, $31.00*

The patient with clinically significant depression

He's getting better... and ELAVIL®

(AMITRIPTYLINE HCl | MSD

is helping

Helping with symptom relief

ELAVIL usually relieves a broad range of symptoms associated with depression, including sleep disturbance, one of the most frequently observed in the "constellation of symptoms," and usually the first symptom to respond to therapy.

And, the anxiety-reducing sedative component extends the drug's clinical value when depression is accompanied by symptoms of anxiety. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol.

Helping with convenient dosage regimens

ELAVIL offers a variety of convenient dosage regimens. A once-daily bedtime regimen may be an effective prescribing option, particularly when taken by a depressed patient experiencing sleep disturbance. ELAVIL can also be prescribed in divided daily doses. Prescriptions should be written for the smallest amount feasible.

Providing a wide range of tablet strengths

ELAVIL offers six color-coded tablets, available in the following strengths: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg. And for special circumstances, an injectable form is available. Injection ELAVIL is supplied in 10-ml vials, 10 mg/ml.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

Elavil®

AMITRIPTYLINE HCl (MSD)

Helping relieve the symptoms of clinically significant depression

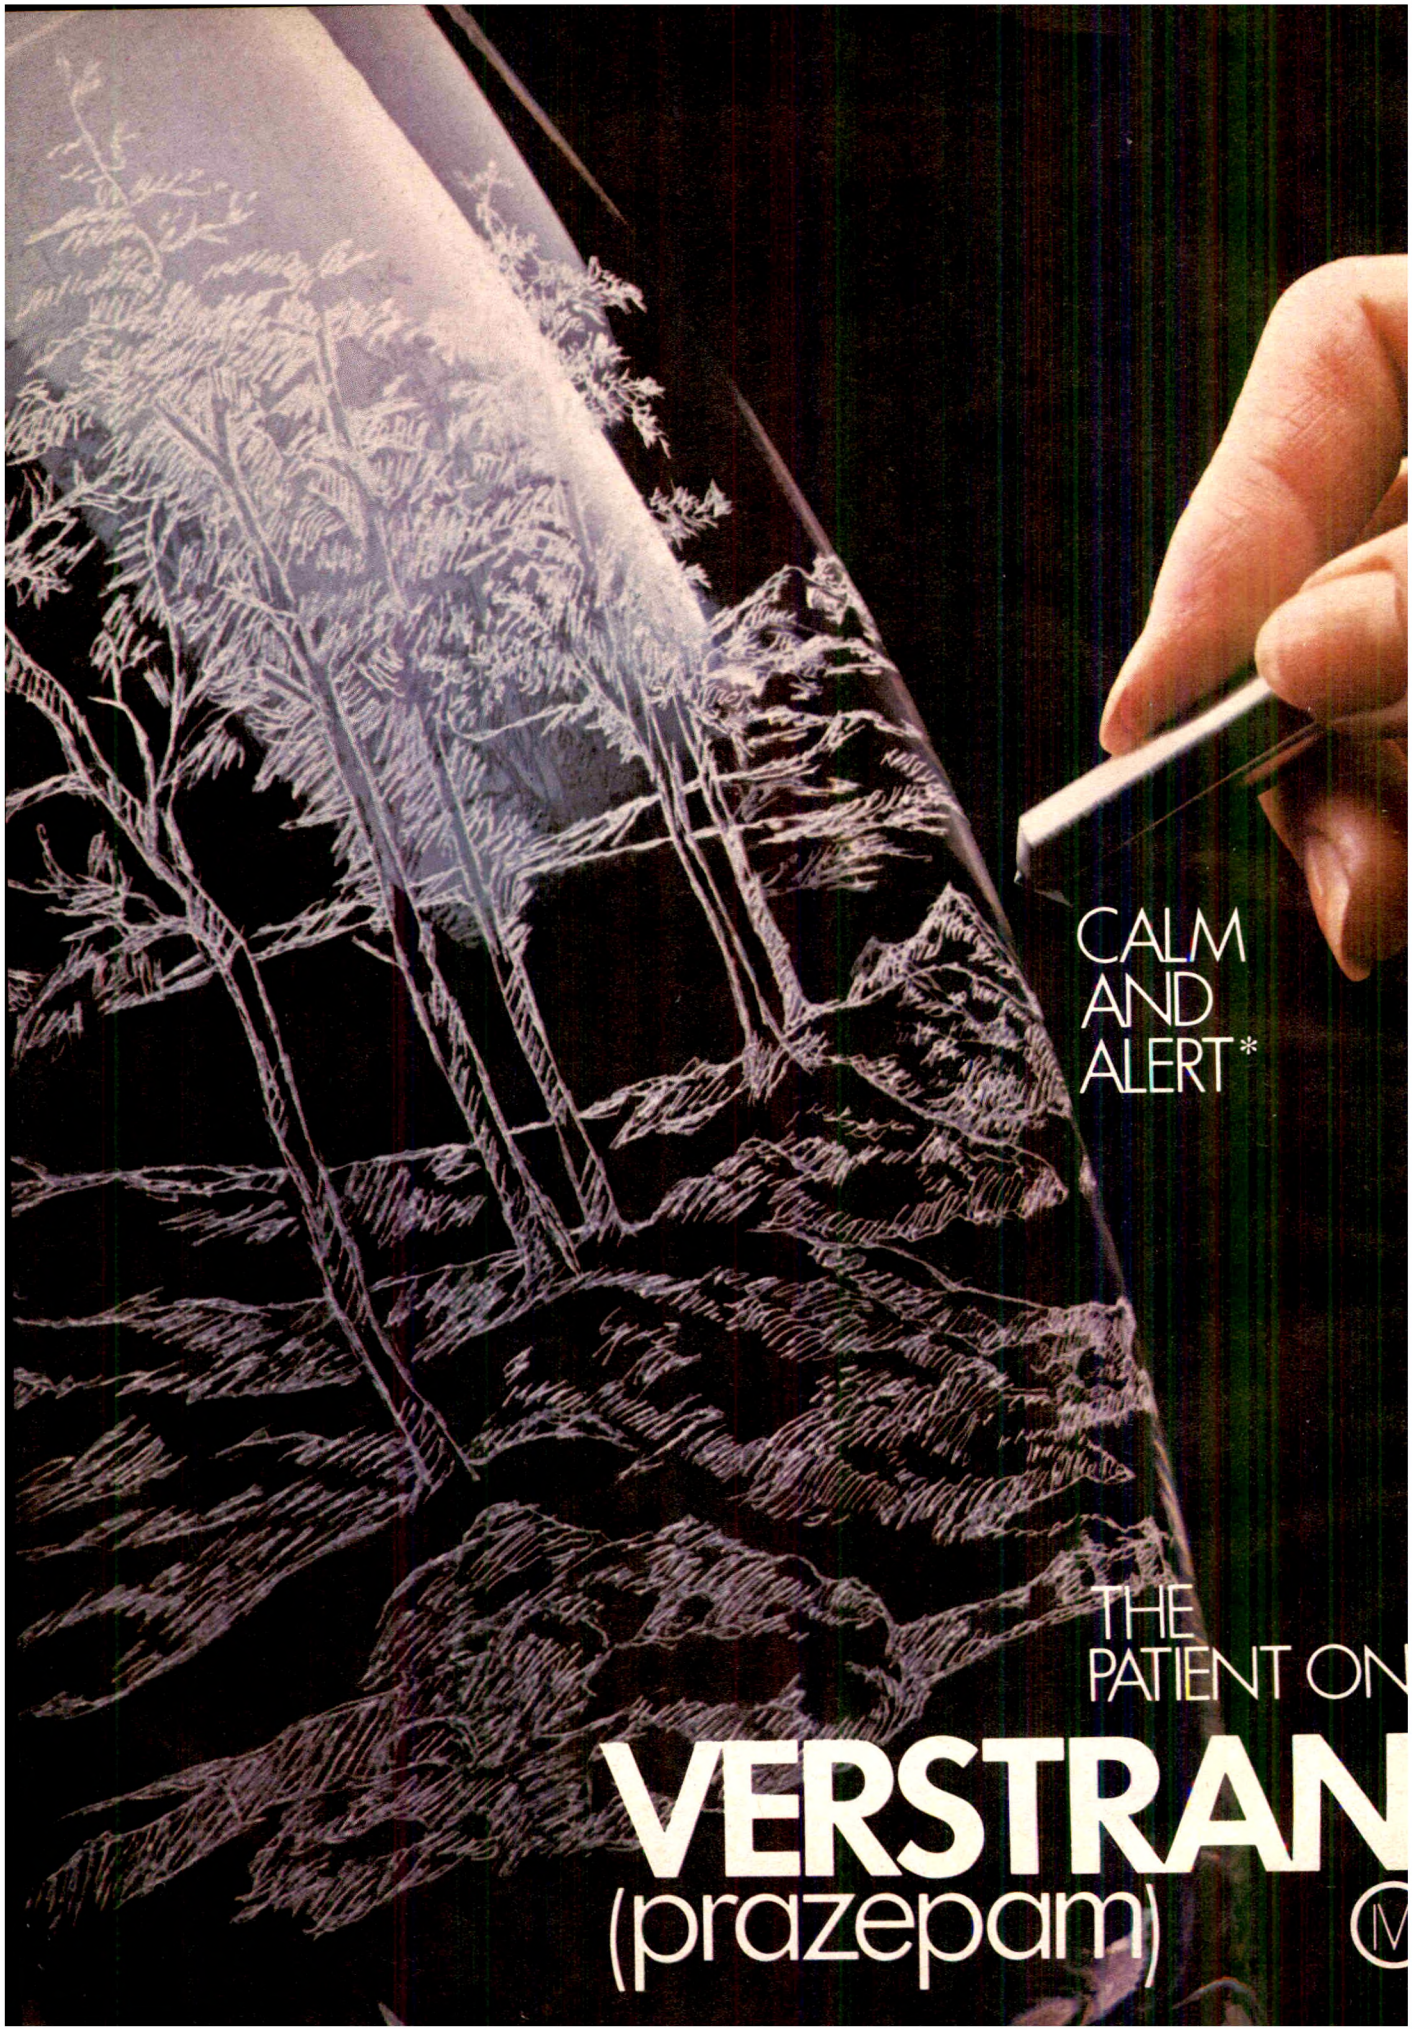
MSD
MERCK SHARP & DOHME

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

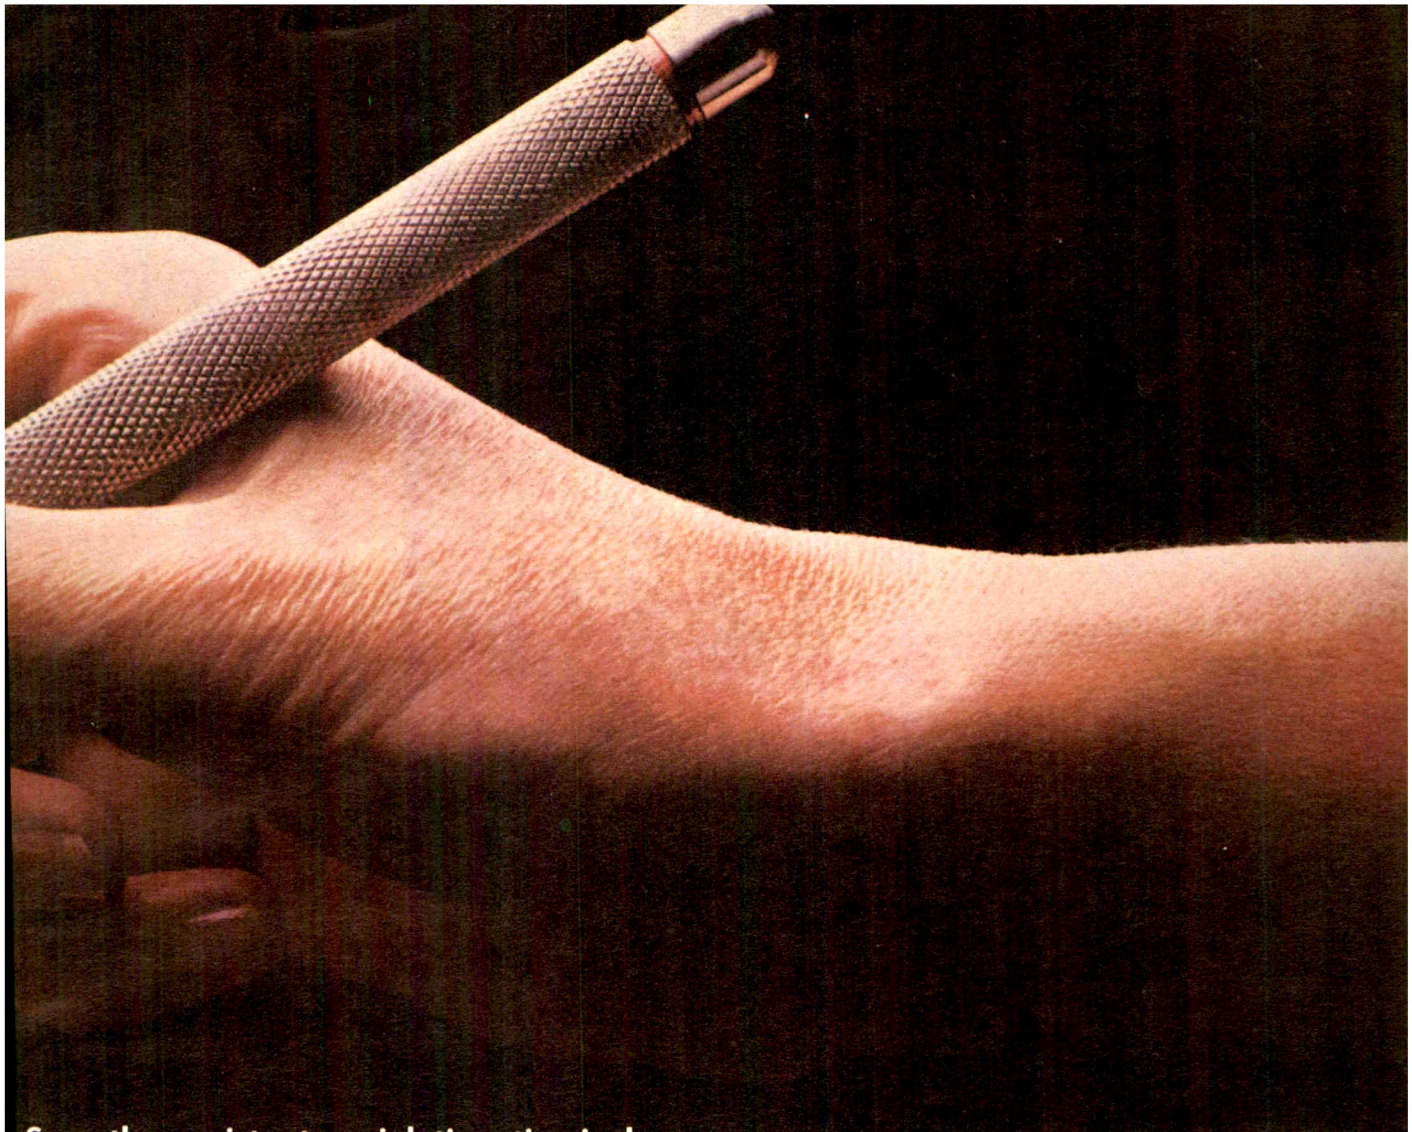
Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.



Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.



Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486

CALM
AND
ALERT*
THE
PATIENT ON
VERSTRAN
(prazepam)
M

Smooth, consistent anxiolytic action is the reason.

Proven efficacy

- Effective symptomatic relief of anxiety, whether psychic or somatic in origin
- Therapeutic response achieved with first dose
- Verstran—a suitable antianxiety alternative to diazepam

Established safety

- Virtually no drowsiness* in most Verstran patients (less than 10%)
- Other side effects, if present, are minimal†
- Verstran is appropriate concomitant therapy in most somatic disorders‡
- No accumulation after steady state is reached

Dosage versatility

- The simplicity of a single-strength 10-mg scored tablet, for easy titration and improved patient compliance
- The flexibility of *once daily*§ dosage
- The option of a *b.i.d.* dosage regimen, gradually adjustable within a range of 20 to 60 mg/day

*As with all CNS-acting agents, patients should be cautioned against driving, drinking, or engaging in hazardous activities.

†Data on file, Warner/Chilcott Medical Department.

TO ENHANCE PATIENT RESPONSIVENESS CONSIDER

VERSTRAN (prazepam) Ⓒ IV

VERSTRAN® (prazepam) Ⓒ IV

Caution: Federal law prohibits dispensing without prescription.

Description: Verstran (prazepam), a benzodiazepine derivative, is identified chemically as 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one. The molecular weight is 324.8 and the structural formula is as follows:

Clinical Pharmacology: Studies in normal subjects have shown that Verstran (prazepam) has depressant effects on the central nervous system. Oral administration of single doses as high as 60 mg and divided doses up to 100 mg t.i.d. (300 mg total daily dose) were without toxic effects.

Single oral doses of Verstran in normal subjects produced peak blood levels at 6 hours postadministration, with significant amounts still present after 48 hours. Verstran was slowly absorbed over a prolonged period, rather constant blood levels were maintained, and excretion was prolonged. The mean half-life of prazepam measured in subjects given 10 mg t.i.d. for one week was 63 (±15 s.d.) hours before and 70 (±10 s.d.) hours after multiple dosing — a nonsignificant difference. Human metabolism studies showed that prior to elimination from the body, prazepam is metabolized in large part to 3-hydroxyprazepam and oxazepam.

Indications: Verstran (prazepam) is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

The effectiveness of Verstran (prazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

Contraindications: Verstran (prazepam) is contraindicated in patients with a known sensitivity to the drug and in those with acute narrow angle glaucoma.

Warning: Verstran (prazepam) is not recommended in psychotic states and in those psychiatric disorders in which anxiety is not a prominent feature.

Patients taking Verstran should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery, including motor vehicles.

Because Verstran has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, including phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. The effects of alcohol may also be increased.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions:

Use in Pregnancy and Lactation:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Verstran (prazepam) a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug. In view of their molecular size, Verstran and its metabolites are probably excreted in human milk. Therefore, this drug should not be given to nursing mothers.

In those patients in whom a degree of depression accompanies the anxiety, suicidal tendencies may be present, and protective measures may be required. The least amount of drug that is feasible should be available to the patient at any one time.

Patients taking Verstran for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed. Hepatomegaly and cholestasis were observed in chronic toxicity studies in rats and dogs.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

Pediatric Use: Safety and effectiveness in patients below the age of 18 have not been established.

Adverse Reactions: The side effects most frequently reported during double-blind placebo-controlled trials employing a typical 30 mg divided total daily dose and the percent incidence in the Verstran (prazepam) group were: fatigue (11.6%), dizziness (8.7%), weakness (7.7%), drowsiness (6.8%), lightheadedness (6.8%), and ataxia (5.0%). Less frequently reported were: headache, confusion, tremor, vivid dreams, slurred speech, palpitation, stimulation, dry mouth, diaphoresis, and various gastrointestinal complaints. Other side effects included: pruritus, transient skin rashes, swelling of feet, joint pains, various genitourinary complaints, blurred vision, and syncope. Single nightly dose, controlled trials of variable dosages showed a dose-related incidence of these same side effects. Transient and reversible aberrations of liver function tests have been reported, as have slight decreases in blood pressure and increases in body weight.

These findings are characteristic of benzodiazepine drugs.

Overdosage: As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

If vomiting has not occurred spontaneously, it should be induced. Immediate gastric lavage is also recommended. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension though unlikely, may be controlled with Levophed® (levarterenol bitartrate) or Aramine® (metaraminol bitartrate). Caffeine and Sodium Benzoate Injection USP, may be used to counteract central nervous system depressant effects.

Dosage and Administration: Verstran (prazepam) is administered orally in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 20 to 60 mg daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a divided daily dose of 10 mg to 15 mg. (See Precautions.)

Prazepam may also be administered as a single dose daily at bedtime. The recommended starting nightly dose is 20 mg. The response of the patient to several days' treatment will permit the physician to adjust the dose upward or, occasionally, downward to maximize antianxiety effect with a minimum of daytime drowsiness. The optimum dosage will usually range from 20 to 40 mg.

Drug Interactions: If Verstran (prazepam) is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If Verstran is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

How Supplied: Verstran (prazepam) 10 mg light blue scored tablets in bottles of 100 (N 0047-0276-51) and 1000 (N 0047-0276-60).

STORE BETWEEN 59°–86° F (15°–30° C).

The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

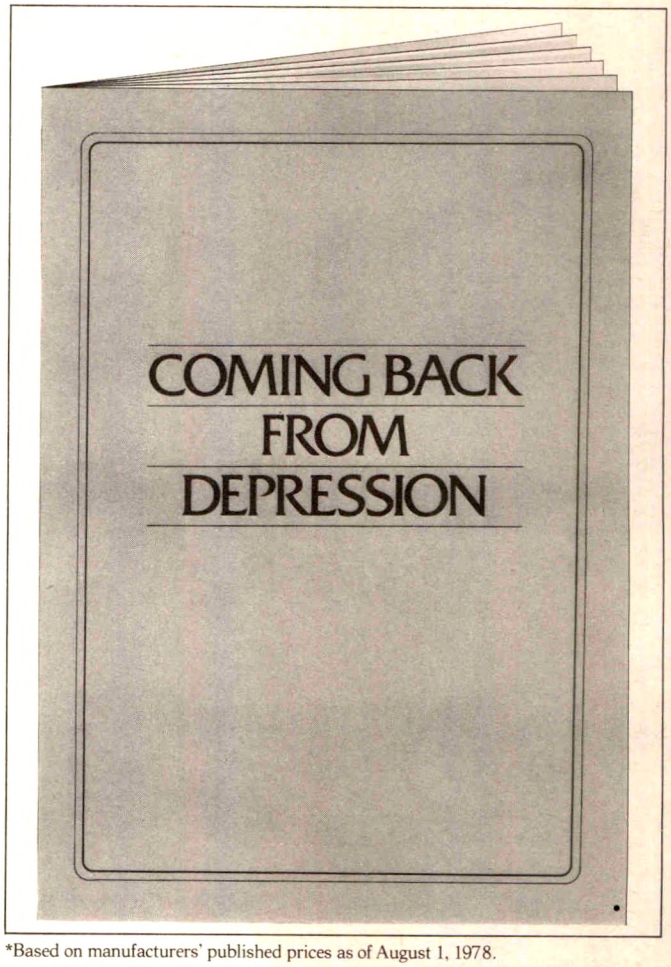
THE BROWN SCHOOLS

An equal opportunity employer. All our programs are accredited by the appropriate Councils of the Joint Commission on Accreditation of Hospitals.

You know what to expect from antidepressant therapy;



...but does your patient?

You know that it generally takes two or three weeks for tricyclic therapy to begin working in depression...and that some side effects may be encountered. But, in all likelihood, your patient doesn't.

To lessen the time you spend in explanation and to increase patient compliance, we've prepared a special patient information booklet in conjunction with the introduction of Amitid—a high quality, low cost amitriptyline from Squibb. Entitled "COMING BACK FROM DEPRESSION," this booklet offers encouragement to depressed patients, helps you explain the basic facts about depression and outlines some of the things to be expected during therapy, the good *and* the bad.

You can get a supply of this carefully written booklet simply by sending a request on your letterhead to E. R. Squibb & Sons, Inc., Department 31, P.O. Box 4000, Princeton, New Jersey 08540. And you can save your patients significant amounts of money by specifying Amitid on all your amitriptyline prescriptions.

Amitid is available in five separate strengths, and is bioequivalent to the leading brand of amitriptyline. Amitid offers all the known clinical advantages of amitriptyline—relieving a wide range of depression-associated symptoms. Yet Amitid is priced considerably lower than other leading brands;* bringing savings that should help ease the burden of depression for patients...just a little bit more!

*Based on manufacturers' published prices as of August 1, 1978.

Introducing

Amitid™

Amitriptyline Hydrochloride Tablets USP

lowers the cost, not the quality, of antidepressant therapy

Please see following page for brief summary.

SQUIBB®

Amitid™ (Amitriptyline Hydrochloride Tablets USP)

DESCRIPTION: Amitriptyline hydrochloride is a dibenzocycloheptadiene derivative available for oral administration as FILMLOK® tablets (FILMLOK is a Squibb trademark for veneer-coated tablets).

INDICATIONS: For relief of symptoms of depression alone or accompanied by anxiety. Endogenous depression is more likely to be alleviated than are other depressive states.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to amitriptyline. Do not administer concomitantly with a monamine oxidase (MAO) inhibitor since hyperpyretic crises, severe convulsions, and deaths occurred when tricyclic antidepressants and MAO inhibitors were administered simultaneously. When an MAO inhibitor is to be replaced by amitriptyline, allow 14 days to elapse after discontinuation of the former and then initiate amitriptyline cautiously and gradually increase dosage until optimum response is achieved. Amitriptyline is not recommended for use during the acute recovery phase following myocardial infarction.

WARNINGS: Amitriptyline may block antihypertensive action of guanethidine or similarly acting drugs. Use with caution in patients with history of seizures and (because of atropine-like action of amitriptyline) in patients with history of narrow-angle glaucoma (even average doses may precipitate an attack), increased intraocular pressure, or urinary retention. Closely watch patients with cardiovascular disorders since, in addition to having caused myocardial infarction and stroke, tricyclic antidepressants (including amitriptyline) particularly with high dosage have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Close supervision is required when amitriptyline is given to hyperthyroid patients or those on thyroid medication. Amitriptyline may impair mental and/or physical abilities required for performance of hazardous tasks such as operating machinery or driving a motor vehicle. Bear in mind that in patients who may use alcohol excessively the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Usage in Pregnancy: Safe use during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women who may become pregnant, weigh the possible benefits against the possible hazards to the mother and child. Animal reproduction studies have been inconclusive, and clinical experience has been limited.

Usage in Children: At the present time, not recommended for patients under 12 years of age because of lack of experience with use in children.

PRECAUTIONS: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances the dose of amitriptyline may be reduced or a major tranquilizer may be administered concurrently.

Closely supervise and carefully adjust dosage in concomitant use with anticholinergic or sympathomimetic drugs, including combination of epinephrine and local anesthetics. Paralytic ileus may occur with concomitant use of tricyclic antidepressants and anticholinergic-type drugs. Caution is advised if used concurrently with large doses of ethchlorvynol since transient delirium has been reported when one gram of that drug and 75 to 150 mg of amitriptyline HCl were administered. Amitriptyline may enhance response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs. Potentially suicidal patients should not have easy access to large quantities of the drug. Prescriptions should be written for the smallest amount feasible. Limit concurrent administration of this drug and electroshock therapy to patients for whom it is essential since the hazards associated with such therapy may be increased. Discontinue this drug, when possible, several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use amitriptyline with caution in presence of impaired liver function.

ADVERSE REACTIONS: NOTE: A few of the adverse reactions listed below have not been reported with this specific drug, but each of the reactions should be considered when administering amitriptyline because of pharmacological similarities among tricyclic antidepressants.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, and stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness; tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; and syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, and dilatation of the urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, and edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, and thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, and black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, and elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, and alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available for oral administration in tablets providing 10, 25, 50, 75, and 100 mg amitriptyline hydrochloride. The 10, 25, and 50 mg tablets are available in bottles of 100 and 1000. The 75 and 100 mg tablets are available in bottles of 100.

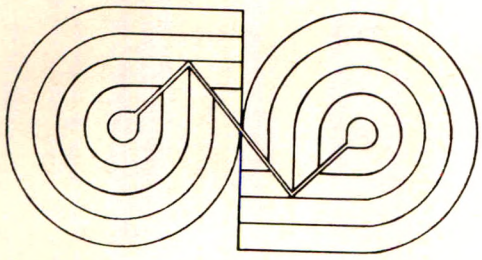
SQUIBB®

He has five years to fight for your life

He is an American Heart Association Established Investigator, funded for five years to work on some phase of cardiovascular disease. He and his associates are researching ways to recognize a heart attack before severe damage occurs.

His ultimate goal is to decrease the present toll from cardiovascular diseases. Of the four Americans that die every minute this year from all causes, two will die from these diseases.



He is one of over 1,400 scientists supported by the American Heart Association who are fighting for your life.

But we need more money for more research that may produce earlier detection and better methods of treatment and prevention of cardiovascular diseases.

When a Heart Association volunteer asks for your money, think of the 1,400 scientific investigators. Help them fight for your life.

Please give generously to the American Heart Association.

WE'RE FIGHTING FOR YOUR LIFE

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

proven antianxiety

Highly specific calming action virtually free of unwanted side effects: this was the remarkable clinical promise of Librium (chlordiazepoxide HCl). And today this promise continues to be fulfilled in a wide variety of patients you see every day.

ROCHE

The published record on Librium is enormous. So large, in fact, it had to be put into a computer data bank and retrieval system. It's a record that shows Librium is highly effective in relieving anxiety; that Librium is seldom associated with serious side effects; that Librium rarely interferes with mental acuity at proper doses; that Librium is used concomitantly with primary medications. However, as with all CNS agents, patients should be warned against hazardous activities requiring complete alertness, and about possible combined effects with alcohol.

performance

Librium® IV

chlordiazepoxide HCl/Roche

5mg, 10mg, 25mg capsules

synonymous with relief of anxiety

- ☐ An unsurpassed safety record
- ☐ Minimal effect on mental acuity, in proper dosage
- ☐ Predictable patient response
- ☐ Is used concomitantly with primary medications, such as anticholinergics and cardiovascular drugs

Please see next page for summary of product information.

Librium® 5mg, 10mg, 25mg capsules
chlordiazepoxide HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states. Efficacy beyond four months not established by systematic clinical studies. Periodic reassessment of therapy recommended.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Warn patients that mental and/or physical abilities required for tasks such as driving or operating machinery may be impaired, as may be mental alertness in children, and that concomitant use with alcohol or CNS depressants may have an additive effect. Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Usual Daily Dosage: Individualize for maximum beneficial effects. *Oral–Adults:* Mild and moderate anxiety and tension, 5 or 10 mg *t.i.d.* or *q.i.d.*; severe states, 20 or 25 mg *t.i.d.* or *q.i.d. Geriatric patients:* 5 mg *b.i.d.* to *q.i.d.* (See Precautions.)

Supplied: Librium® (chlordiazepoxide HCl) *Capsules*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10. Libritabs® (chlordiazepoxide) *Tablets*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500. With respect to clinical activity, capsules and tablets are indistinguishable.

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

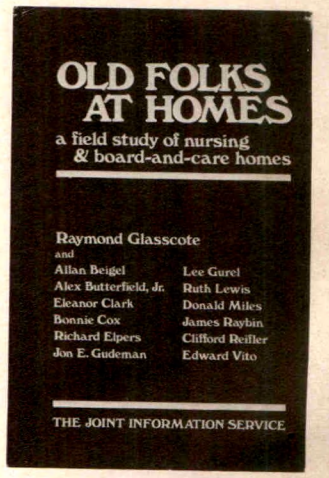
Focus on the Elderly

This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."



190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

ADRIFT IN A SEA OF CONFUSING VOICES

'STELAZINE' HELPS FIND THE WAY BACK

The schizophrenic patient is often surrounded by confusing voices, bewildering thoughts, fright and anxiety. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, convenient b.i.d. 'Stelazine' usually does not cause excessive sedation, which means that 'Stelazine' works with and not against your therapeutic program.

After 18 years of extensive research and clinical experience, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer side effects than 'Stelazine'. These facts make 'Stelazine' a first choice for therapy.

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

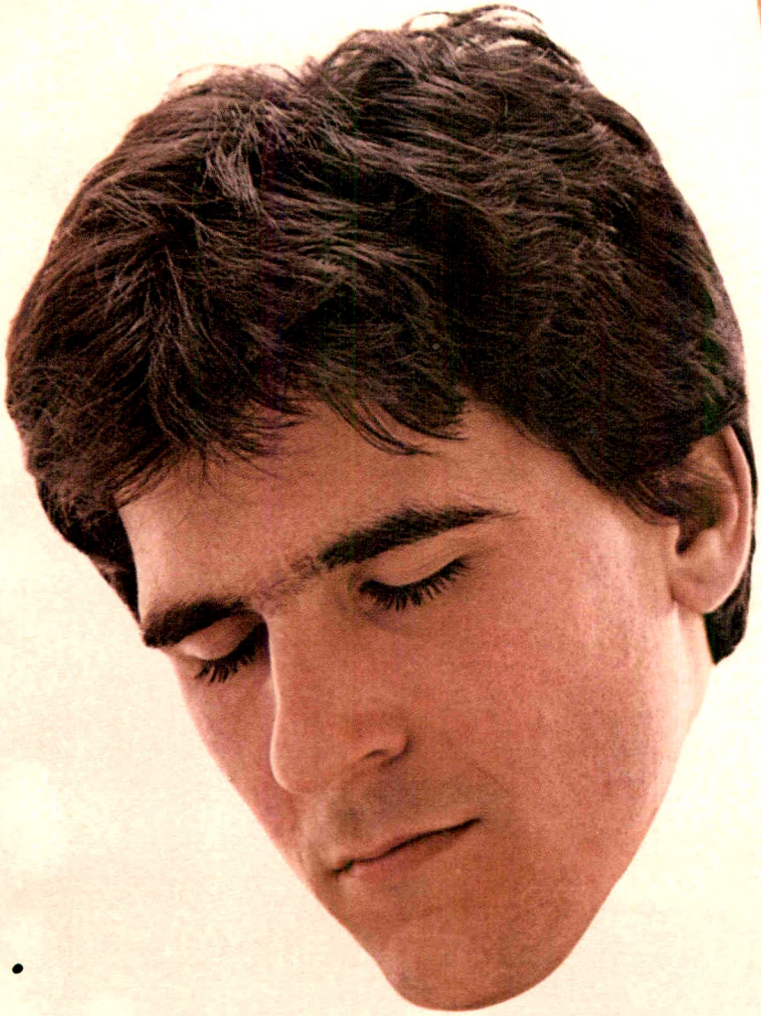
TABLETS: 5 and 10 mg

brand of

TRIFLUOPERAZINE HCl



A First Choice for Therapy

THE MANY FACES

Help for the apathetic/ withdrawn geriatric*

For the aged person suffering from withdrawn or apathetic senile behavior, Ritalin can often help relieve bothersome symptoms. In one double-blind study[1] of withdrawn, apathetic geriatric patients, Ritalin elicited notable improvement in competence, interest and retardation. While no side effects were reported in this study, blood pressure and pulse variations were noted in both groups but were not considered of exceptional magnitude.

Help for narcoleptic patients

The narcoleptic patient can fall asleep anytime...anyplace... and the consequences can be grave, or at the least, embarrassing. Although there is no known cure for narcolepsy, Ritalin acts promptly to counteract sleepiness and is the medication most frequently used by cited investigators.[2,3] Occasional problems of tolerance may be managed by complete withdrawal of Ritalin during vacation or holidays, then reinstating the drug at lower dosage.[3]

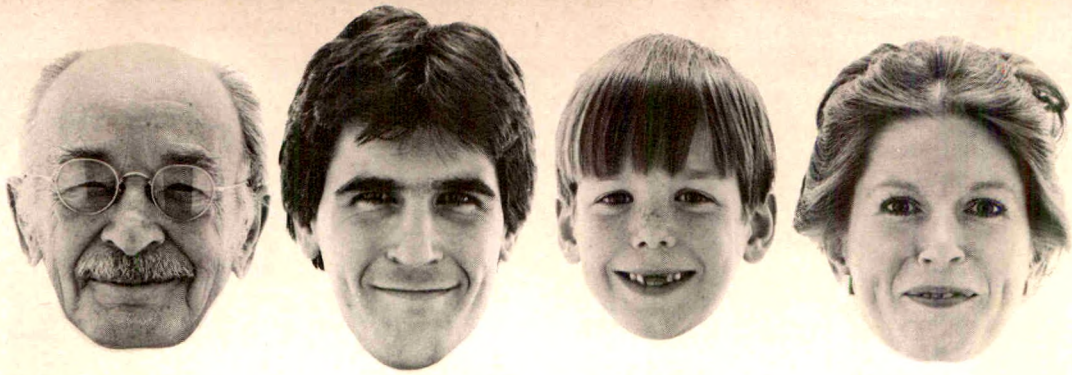
Ritalin has been evaluated as possibly effective in these indications.

OF RITALIN® C II

(methylphenidate)

Help for patients with mild depression*

As Ritalin acts promptly to relieve symptoms of mild depression, mood and outlook usually improve, and the patient can cope again. Generally, one prescription is sufficient. Ritalin is contraindicated in severe depression.



Help for the MBD child

For the child with Minimal Brain Dysfunction (MBD), adjunctive Ritalin is often highly effective when medication is needed to help reduce symptoms such as distractibility,[4] disorganized behavior,[4] and hyperactivity.[4] MBD children responding to Ritalin usually exhibit better classroom performance and improved interpersonal relationships. Moreover, as MBD symptoms are curbed, the affected child often responds more positively to nonpharmacologic modalities.[5] Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is temporarily or permanently discontinued.

SO MUCH HELP FOR SO MANY PATIENTS

Ritalin® hydrochloride C
(methylphenidate hydrochloride USP)

TABLETS

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)
Special Diagnostic Considerations
Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.
Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.
Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.
Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.
Effective: Narcolepsy
"Possibly" effective: Mild Depression; Apathetic or Withdrawn Senile Behavior
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS
Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.
Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (*ie*, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.
Ritalin should not be used for severe depression of either exogenous or endogenous origin.
Ritalin should not be used for the prevention or treatment of normal fatigue states.
There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.
Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.
Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions
Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.
Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy
Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence
Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.
Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS
Patients with an element of agitation may react adversely; discontinue therapy if necessary.
Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS
Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been reported. Although a definite causal relationship has not been established, the following have been reported in patients taking this drug: leukopenia and/or anemia; few instances of scalp hair loss.
In children, loss of appetite, abdominal pain, weight loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however, any of the other adverse reactions listed above may also occur.

DOSAGE AND ADMINISTRATION
Adults
Administer orally in divided doses 2 or 3 times daily, preferably 30 to 45 minutes before meals. Dosage will depend upon indication and individual response.
Average dosage is 20 to 30 mg daily. Some patients may require 40 to 60 mg daily. In others, 10 to 15 mg daily will be adequate. Patients who are unable to sleep if medication is taken late in the day should take the last dose before 6 p.m.
Children with Minimal Brain Dysfunction
(6 years and over)
Start with small doses (*eg*, 5 mg before breakfast and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-month period, the drug should be discontinued.
If paradoxical aggravation of symptoms or other adverse effects occur, reduce dosage, or, if necessary, discontinue the drug.
Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is either temporarily or permanently discontinued.
Drug treatment should not and need not be indefinite and usually may be discontinued after puberty.

HOW SUPPLIED
Tablets, 20 mg (peach, scored): bottles of 100 and 1000.
Tablets, 10 mg (pale green, scored): bottles of 100, 500, 1000 and Accu-Pak® blister units of 100.
Tablets, 5 mg (pale yellow): bottles of 100, 500 and 1000.

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL™ 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked agitation with depression

dual-action® **Triavil**

containing perphenazine and amitriptyline HCl

MSD
MERCK SHARP & DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action TRIAVIL®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia) and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

rescribing Information for

Lidone™ (molindone hydrochloride)

ESCRIPTION — LIDONE (molindone hydrochlo-e) is a dihydroindolone compound which is not ucturally related to the phenothiazines, the tyrophenones or the thioxanthenes.
LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(mor-olinomethyl) indol-4(5H)-one hydrochloride. It a white crystalline powder, freely soluble in ter and alcohol and has a molecular weight of 2.67.

CTIONS — LIDONE (molindone hydrochloride) s a pharmacological profile in laboratory mals which predominantly resembles that of jor tranquilizers causing reduction of spon-eous locomotion and aggressiveness, suppres-n of a conditional response and antagonism of bizarre stereotyped behavior and hyperactivity uced by amphetamines. In addition, LIDONE an-onizes the depression caused by the tranquiliz-agent tetrabenazine.
n human clinical studies tranquilization is ieved in the absence of muscle relaxing or in-rdinating effects. Based on EEG studies, ONE exerts its effect on the ascending reticular ivating system.
Human metabolic studies show LIDONE (molin-e hydrochloride) to be rapidly absorbed and tabolized when given orally. Unmetabolized g reached a peak blood level at 1.5 hours. Phar-cological effect from a single oral dose persists 24 to 36 hours. There are 36 recognized tabolites with less than 2 to 3% unmetabolized ONE being excreted in urine and feces.

DICATIONS — LIDONE (molindone hydrochlo-e) is indicated in the management of the nifestations of schizophrenia.

NTRAINDICATIONS — LIDONE (molindone rochloride) is contraindicated in severe central vous system depression (alcohol, barbiturates, cotics, etc.) or comatose states, and in patients h known hypersensitivity to the drug.

RNINGS

ge in Pregnancy: Studies in pregnant pa-ts have not been carried out. Reproduction dies have been performed in the following mals:

gnant Rats Oral Dose —
mg/kg/day — 10 days, no adverse effect
mg/kg/day — 10 days, no adverse effect

gnant Mice Oral Dose —
mg/kg/day — 10 days, slight increase resorp-s
mg/kg/day — 10 days, slight increase resorp-s

gnant Rabbits Oral Dose —
g/kg/day — 12 days, no adverse effect
ng/kg/day — 12 days, no adverse effect
ng/kg/day — 12 days, no adverse effect

mal reproductive studies have not demon-ted a teratogenic potential. The anticipated efits must be weighed against the unknown s to the fetus if used in pregnant patients.

rsing Mothers: Data are not available on the tent of LIDONE (molindone hydrochloride) in milk of nursing mothers.

ge in Children: Use of LIDONE (molindone rochloride) in children below the age of twelve rs is not recommended because safe and effec-conditions for its usage have not been estab-ed.

ECAUTIONS — Some patients receiving ONE (molindone hydrochloride) may note vsiness initially and they should be advised nst activities requiring mental alertness until r response to the drug has been established.
creased activity has been noted in patients iving LIDONE. Caution should be exercised re increased activity may be harmful.
DONE does not lower the seizure threshold in rimental animals to the degree noted with e sedating antipsychotic drugs. However, con-ive seizures have been reported in a few ances.
DONE has an antiemetic effect in animals. A lar effect may occur in humans and may ure signs of intestinal obstruction or brain or.

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION — Initial and maintenance doses of LIDONE (molindone hydrochloride) should be individualized.

Initial Dosage Schedule

The usual starting dosage is 50 to 75 mg/day.
- — Increase to 100 mg/day in three or four days.
- — Based on severity of symptomatology, dosage may be titrated up or down depending on individual patient response.
- — An increase to 225 mg/day may be required in patients with severe symptomatology.
- — Some chronic, treatment-resistant patients may require up to 400 mg/day; (however, the long-term safety of 400 mg/day has not been established).

Elderly or debilitated patients should be started on lower dosage.

Maintenance Dosage Schedule

1. Mild — 5 mg to 15 mg three or four times a day.
2. Moderate — 10 mg to 25 mg three or four times a day.
3. Severe — 225 mg/day may be required.

Dosage may be administered once a day.

DRUG INTERACTIONS — Potentiation of drugs administered concurrently with LIDONE (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when LIDONE is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE — Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of LIDONE (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of LIDONE (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by LIDONE in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized LIDONE from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of LIDONE is excreted unmetabolized in the urine.) However, poor response of the patient may justify use of these procedures.

While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized LIDONE in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED — LIDONE (molindone hydrochloride) capsules are supplied in bottles of 100 in the following dosage strengths and colors:

5 mg (**NDC** 0074-5542-13) blue and cream
10 mg (**NDC** 0074-5543-13) red and cream
25 mg (**NDC** 0074-5544-13) brown and cream

TM — Trademark
*Benadryl — Trademark, Parke Davis and Co.
*Artane — Trademark, Lederle Laboratories
*Cogentin — Trademark, Merck Sharp & Dohme
*Akineton — Trademark, Knoll Pharmaceutical Co.

Treats schizophrenic target symptoms

with less likelihood of certain troublesome effects

5, 10, 25 mg capsules

Lidone™
(Molindone HCl)

See overleaf for prescribing information

Significant gains are reported in control of hallucinations, conceptual disorganization, hostility, unusual thought content, emotional withdrawal.

Yet no reports of persistent tardive dyskinesia, excessive weight gain, impotence, lens opacities, skin pigmentation; and only rare cases of significant hypotension. Other side effects are similar to comparable agents.

OFFICIAL JOURNAL OF THE AMERICAN PSYCHIATRIC ASSOCIATION

ADRIFT IN A SEA OF CONFUSING VOICES

'STELAZINE' HELPS FIND THE WAY BACK

The schizophrenic patient is often surrounded by confusing voices, bewildering thoughts, fright and anxiety. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, convenient b.i.d. 'Stelazine' usually does not cause excessive sedation, which means that 'Stelazine' works with and not against your therapeutic program.

After 18 years of extensive research and clinical experience, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer side effects than 'Stelazine'. These facts make 'Stelazine' a first choice for therapy.

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

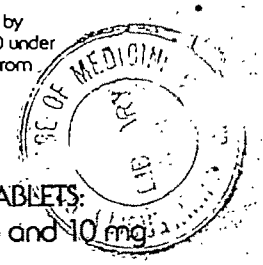
Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.



Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./mL; and Concentrate (intended for institutional use only), 10 mg./ml.

A First Choice for Therapy

Basic Books, Inc. proudly announces a landmark in child psychiatry— the first truly encyclopedic work in this rapidly advancing field.

Basic Handbook of Child Psychiatry

In Four Volumes
JOSEPH D. NOSHPITZ, M.D., *Editor-in-Chief*
Past President, American Academy of Child Psychiatry

Child psychiatry and all the disciplines impinging upon it have expanded rapidly in recent years. But until now, there has been no comprehensive, systematic, up-to-date reference to the full scope of knowledge in this field.

Now the **Basic Handbook of Child Psychiatry** fills this need. For the first time in three decades, it brings together in a four-volume reference all the developments—in clinical practice as well as in academic theory—of vital importance to every professional whose work is focused upon the child.

The **Handbook** systematically covers the entire period of child development—from conception to the end of adolescence. Among its salient features:

- Current research on children of different backgrounds, lifestyles, religious patterns, and economic groups in America.
- A full account of the theory and practice of evaluating children and making a diagnostic profile.
- A considerably detailed examination of disturbances in development, focused on etiology, nosology, and syndromes.
- A comprehensive presentation of the full range of therapeutic interventions, covering in detail the following therapies: individual, family and group, counseling, consultation, biological, and special.
- A complete overview of primary, secondary, and tertiary approaches to the prevention of children's psychiatric problems.
- A penetrating look at the impact of major cultural trends on children, families, and the practice of child psychiatry.

Carefully designed by practitioners for the practitioner, the **Handbook** represents the collective expertise of over 300 leading authorities—child psychiatrists, psychologists, geneticists, neurologists, developmental biochemists, educators, social workers, and mental health administrators... professionals actually working with virtually every segment of the American population.

Their contributions, all originally written for the **Handbook,** cover the entire field systematically and to a depth which is truly unique.

Now, for a limited time only, you may own the entire four-volume set at a prepublication discount of almost one-third off the list price. You have 14 days in which to study, examine, and use the first two volumes—at our risk. The last two volumes will be sent, under the same 14-day guarantee, as soon as they are off press.

Just check the appropriate box on the order form below, and return it before May 15, 1979.

Volume I: **Development**
Edited by *Justin Call, M.D.*
University of California (Irvine),
Joseph D. Noshpitz, M.D.,
George Washington University,
Irving N. Berlin, M.D., University of New Mexico, and
Richard L. Cohen, M.D., Pittsburgh Child Guidance Center.
768 pp. Due April 25, 1979.

Volume II: **Disturbances In Development**
Edited by *Joseph D. Noshpitz, M.D.*,
George Washington University.
784 pp. Due April 25, 1979.

Volume III: **Therapeutic Interventions**
Edited by *Saul Harrison, M.D.*,
Children's Psychiatric Hospital
University of Michigan Medical Center.
786 pp. Due January, 1980.

Volume IV: **Prevention and Current Issues**
Edited by *Irving N. Berlin, M.D.*,
University of New Mexico
and *Lawrence A. Stone, M.D.*,
University of Texas Health Sciences Center.
752 pp. Due January, 1980.

To: BASIC BOOKS, INC.
10 East 53 St., New York, NY 10022

Yes, I want to be among the first to receive **The Basic Handbook of Child Psychiatry** as soon as the first printing is off press. Send me:

☐ The four-volume set for only $99.50—a special prepublication discount of nearly one-third off the list price of $138.00. I will receive Volume I, **Development,** and Volume II, **Disturbances in Development,** on or about April 25; and the remaining volumes as soon as printing is completed on or about January, 1980. Add *$4.25* for shipping and handling.

I have fourteen days to study and use the first two volumes before deciding whether I want to receive the entire set and can return them for full credit at any time within that period.

☐ Individual volumes as checked here. I understand I have the same 14-day examination and return privilege. ☐ Volume I ☐ Volume II ☐ Volume III ☐ Volume IV at the prepublication discount price of $29.50 each. (List price $35.50) Add $1.25 per volume, for shipping and handling.

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions, and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot

studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality, and authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications (no précis is used in the Clinical and Research Reports section). The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say 'differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material; a complete review of the literature is rarely desirable. *Accuracy of citation is the author's responsibility.* References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do *not* arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below and on the next page, double-spaced *throughout* (not just a line between

references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2-6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

VOICES
.accusatory, derogatory, ondemning, commanding.

Navane (thiothixene) rapidly controls auditory hallucinations as well as agitation and hostility patterns they frequently generate.

Rapid control of psychotic symptoms on admission

Navane provides effective, rapid control of the major symptoms of psychosis luding hallucinations, delusions, agitation, hostility, and thought disorders.[1-5] vane promotes rapid progress, usually without the over-sedation or cardio-cular problems that can impede the therapeutic course.

Continued long-term improvement

Because Navane provides long-term outpatient control of psychotic symptoms, an enable many patients to function effectively at home and on the job and to ist rapidly to the community.[6]

Effectiveness rarely compromised by adverse reactions

Navane allows patients to remain alert and active, seldom causing over-ation or drowsiness.[7] Hypotension and other cardiovascular reactions[5,6,8] are om reported and the occurrence of unpleasant anticholinergic side effects such ry mouth or constipation is rare.[9] If extrapyramidal symptoms occur, they are ally readily controlled through dosage adjustments or antiparkinson agents.

Rapid control
Long-term improvement

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg
(thiothixene hydrochloride) Concentrate: 5 mg/ml,
Intramuscular: 2 mg/ml

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*—Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration—As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate—In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

D.C. Heath and Company of Lexington, Massachusetts, takes pleasure in announcing the formation of a medical publishing house to be called

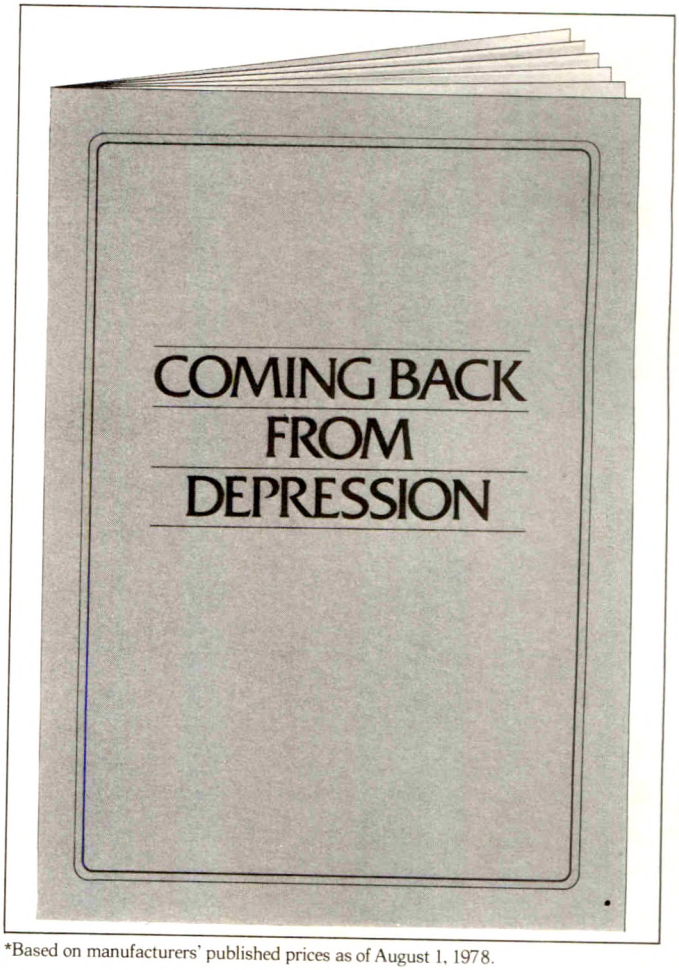
THE COLLAMORE PRESS

D.C. Heath and Company has been a leader in educational and professional publishing since its beginnings in 1885. One out of three Americans has studied from a Heath book. Our offices are in Lexington, Massachusetts, New York, and Toronto.

The new medical program will be conducted by Heath's professional publishing division, Lexington Books. Manuscripts, proposals, and general inquiries may be directed to:

The Editorial Department
The Collamore Press
D.C. Heath and Company
125 Spring Street
Lexington, Massachusetts 02173
(617) 862-6650 (212) 924-6460

You know what to expect from antidepressant therapy;



...but does your patient?

You know that it generally takes two or three weeks for tricyclic therapy to begin working in depression...and that some side effects may be encountered. But, in all likelihood, your patient doesn't.

To lessen the time you spend in explanation and to increase patient compliance, we've prepared a special patient information booklet in conjunction with the introduction of Amitid—a high quality, low cost amitriptyline from Squibb. Entitled "COMING BACK FROM DEPRESSION," this booklet offers encouragement to depressed patients, helps you explain the basic facts about depression and outlines some of the things to be expected during therapy, the good *and* the bad.

You can get a supply of this carefully written booklet simply by sending a request on your letterhead to E. R. Squibb & Sons, Inc., Department 31, P.O. Box 4000, Princeton, New Jersey 08540. And you can save your patients significant amounts of money by specifying Amitid on all your amitriptyline prescriptions.

Amitid is available in five separate strengths, and is bioequivalent to the leading brand of amitriptyline. Amitid offers all the known clinical advantages of amitriptyline—relieving a wide range of depression-associated symptoms. Yet Amitid is priced considerably lower than other leading brands;* bringing savings that should help ease the burden of depression for patients...just a little bit more!

*Based on manufacturers' published prices as of August 1, 1978.

Introducing

Amitid™

Amitriptyline Hydrochloride Tablets USP

lowers the cost, not the quality, of antidepressant therapy

Please see following page for brief summary.

SQUIBB®

Amitid™ (Amitriptyline Hydrochloride Tablets USP)

DESCRIPTION: Amitriptyline hydrochloride is a dibenzocycloheptadiene derivative available for oral administration as FILMLOK® tablets (FILMLOK is a Squibb trademark for veneer-coated tablets).

INDICATIONS: For relief of symptoms of depression alone or accompanied by anxiety. Endogenous depression is more likely to be alleviated than are other depressive states.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to amitriptyline. Do not administer concomitantly with a monamine oxidase (MAO) inhibitor since hyperpyretic crises, severe convulsions, and deaths occurred when tricyclic antidepressants and MAO inhibitors were administered simultaneously. When an MAO inhibitor is to be replaced by amitriptyline, allow 14 days to elapse after discontinuation of the former and then initiate amitriptyline cautiously and gradually increase dosage until optimum response is achieved. Amitriptyline is not recommended for use during the acute recovery phase following myocardial infarction.

WARNINGS: Amitriptyline may block antihypertensive action of guanethidine or similarly acting drugs. Use with caution in patients with history of seizures and (because of atropine-like action of amitriptyline) in patients with history of narrow-angle glaucoma (even average doses may precipitate an attack), increased intraocular pressure, or urinary retention. Closely watch patients with cardiovascular disorders since, in addition to having caused myocardial infarction and stroke, tricyclic antidepressants (including amitriptyline) particularly with high dosage have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Close supervision is required when amitriptyline is given to hyperthyroid patients or those on thyroid medication. Amitriptyline may impair mental and/or physical abilities required for performance of hazardous tasks such as operating machinery or driving a motor vehicle. Bear in mind that in patients who may use alcohol excessively the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Usage in Pregnancy: Safe use during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women who may become pregnant, weigh the possible benefits against the possible hazards to the mother and child. Animal reproduction studies have been inconclusive, and clinical experience has been limited.

Usage in Children: At the present time, not recommended for patients under 12 years of age because of lack of experience with use in children.

PRECAUTIONS: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances the dose of amitriptyline may be reduced or a major tranquilizer may be administered concurrently.

Closely supervise and carefully adjust dosage in concomitant use with anticholinergic or sympathomimetic drugs, including combination of epinephrine and local anesthetics. Paralytic ileus may occur with concomitant use of tricyclic antidepressants and anticholinergic-type drugs. Caution is advised if used concurrently with large doses of ethchlorvynol since transient delirium has been reported when one gram of that drug and 75 to 150 mg of amitriptyline HCl were administered. Amitriptyline may enhance response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs. Potentially suicidal patients should not have easy access to large quantities of the drug. Prescriptions should be written for the smallest amount feasible. Limit concurrent administration of this drug and electroshock therapy to patients for whom it is essential since the hazards associated with such therapy may be increased. Discontinue this drug, when possible, several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use amitriptyline with caution in presence of impaired liver function.

ADVERSE REACTIONS: NOTE: A few of the adverse reactions listed below have not been reported with this specific drug, but each of the reactions should be considered when administering amitriptyline because of pharmacological similarities among tricyclic antidepressants.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, and stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness; tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; and syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, and dilatation of the urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, and edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, and thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, and black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, and elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, and alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available for oral administration in tablets providing 10, 25, 50, 75, and 100 mg amitriptyline hydrochloride. The 10, 25, and 50 mg tablets are available in bottles of 100 and 1000. The 75 and 100 mg tablets are available in bottles of 100.

BOOKS OF DISTINCTION

THE CLASSIFICATION OF ENDOGENOUS PSYCHOSES

Karl Leonhard, *Humboldt University Nerve Clinic, Charité, Berlin, German Democratic Republic;* Edited by **Eli Borins,** translated by **Russell Berman**

The first English translation of this classical German work containing elegant descriptions of phasic psychoses in their pure forms. Intended to make a significant difference in the way psychiatrists and psychologists view psychotic disorders, from manic-depression to schizophrenia. (An Irvington publication)
(0 470 26596-5) 1979 480 pp. $22.50

RESEARCH DESIGN IN CLINICAL PSYCHOLOGY AND PSYCHIATRY
nd Ed., Revised and Enlarged

. B. Chassan, *The George Washington University School of Medicine, Hoffmann-La Roche Inc.*

. rather unique book in the domain of sychiatric research! Many practical roblems which tend to haunt investigaors in psychiatry and psychology appear etween its covers...."

–Archives of General Psychiatry (on the 1st Ed.)

nd Ed. includes an introduction—with illustations—to practically all useful statistical chniques, concepts, and experimental esigns. (An Irvington publication)
470 26577-9) 1979 496 pp. $18.50

ATTERNS OF TTACHMENT
. Psychological Study of ne Strange Situation

ary D. Salter Ainsworth, *University of rginia,* **Mary C. Blehar, Everett Waters, Sally Wall**

xamines infant-mother attachment using e "strange situation" procedure as a means measuring socio-emotional development. ates theory, demonstrates "objectivity," d provides evidence of pattern stability, d its usefulness in predicting future behavrs—giving substantial support to Bowlby's olutionary-ethological theory of attachnt. (A Lawrence Erlbaum Associates blication)
470 26534-5) 1979
1 pp. $24.95

HYPNOTHERAPY
An Exploratory Casebook

Milton Erickson & Ernest Rossi

A continuation of the work begun with the authors' HYPNOTIC REALITIES (Halsted, 1976) which is the record of the senior author's efforts in training the junior author in the field of clinical hypnotherapy. Tape cassette included. (An Irvington publication)
(0 470 26595-7) 1979 544 pp. $34.50

ALTERNATIVES TO PSYCHIATRIC HOSPITALIZATION

Harry Gottesfeld,
City College of New York

Describes alternatives to psychiatric hospitalization—considered in terms of costs, benefits, day-to-day operations, community involvement, and risks. (A Gardner Press publication)
(0 470 99188-7) 1977 131 pp. $11.95

VIOLENCE AND RESPONSIBILITY
The Individual, the Family and Society

Edited by **Robert L. Sadoff,**
University of Pennsylvania & Villanova University School of Law

Several psychiatrists, a neurologist, a criminologist, an historian, a law professor, and a judge present their experience/views on the phenomenon of violence in human society. (A Spectrum publication)
(0 470 26422-5) 1978 139 pp. $14.95

PSYCHIATRIC SYMPTOMS AND COGNITIVE LOSS IN THE ELDERLY
Evaluation and Assessment Techniques

Edited by **Allen Raskin,** *National Institute of Mental Health,* & **Lissy Jarvik,** *Brentwood V.A. Hospital of California, Los Angeles*

Provides the clinician and researcher with the most current analyses of assessment techniques and devices used to evaluate the clinical status of older patients. (A Hemisphere publication)
(0 470 26579-5) April 1979
approx. 300 pp. $20.00

DISORDERED THINKING AND STUDIES IN SCHIZOPHRENIA

Martin Harrow, *University of Chicago,* & **Donald Quinlan,** *Yale University*

A series of investigations of the roles of various cognitive and affective factors in schizophrenia. Systematically brings together concepts relating to thought disorder. (A Gardner Press publication)
(0 479 26507-8) 1979
approx. 425 pp. $22.95

PRIVATE PRACTICE
A Handbook for the Mental Health Practitioner

Robert Pressman

Covers all factors critical to building and maintaining a thriving private practice in the mental health field. Designed to save months or even years of trial and error, it is a must for anyone embarking upon his/her own first independent practice. (A Gardner Press publication)
(0 470 26388-1) 1979 280 pp. $18.95

FROM HALSTED PRESS

Must the MBD child take a controlled drug in school?

Not if he's taking Cylert® (pemoline) C IV

18.75, 37.5, 75 mg tablets

Children can be cruel. Their teasing about taking noontime medication can cause serious problems for the child with MBD.

Here's how Cylert eliminates this problem:

- Once a day dosage at home
- Eliminates mid-day school dose

In addition, Cylert offers these benefits:

- Avoids ups and downs of drug action brought about by multiple daily dosage
- Control of medication by the parent
- A chewable dosage form
- Less physician paper work (Cylert is in schedule IV)
- Safety and efficacy proven in extensive clinical studies*

*Copy of the Cylert Monograph available to Physicians on written request.

When not to use medication

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school-age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

ABBOTT

Please see next page for Prescribing Information.

Cylert and Cylert Chewable Tablets

(pemoline)

Prescribing Information

Indications: *MINIMAL BRAIN DYSFUNCTION IN CHILDREN*—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: The cause of minimal brain dysfunction (MBD) is unknown. Diagnosis of MBD involves the use of medical, psychological, educational, and social tools, since no single diagnostic test is adequate.

MBD is characterized by chronic moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alon are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindications: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

Warnings: Cylert is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Sufficient data on the safety and the efficacy of the long-term use of Cylert in children with minimal brain dysfunction are not yet available.

A temporary suppression of the predicted growth rate (weight and/or height gain) has been reported for children receiving long-term stimulant therapy. A definite causal relationship between stimulant drugs and this finding has not been established.

Precautions: Liver function tests should be performed periodically during therapy with Cylert. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

Cylert should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of Cylert with other drugs has not been studied in humans Patients who are receiving Cylert concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

Cylert failed to demonstrate a potential for self-administration in primates However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with Cylert. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline Cylert should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of Cylert (pemoline) fo use during pregnancy and lactation has not been established.

Fertility, reproduction, and teratology studies were conducted in laborator animals. Pemoline, in doses of 18.75 or 37.5 mg./kg./day, had no effect on th fertility of male or female rats. The drug, when given to pregnant rats (from gestation day 15 through weaning) and to rabbits (from gestation days 6-18) at these same dosage levels, produced no teratogenic or embryotoxic effects, and had no effect on the viability of the young at birth. However, increased incidences of stillbirths and cannibalization were observed when pemoline was given to rats at these dosage levels, beginning 14 days prior to conceptio

Adverse Reactions: Insomnia is the most frequently reported side effect c Cylert; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking Cylert, usually after several months of therapy. These effects appear t be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking Cylert; a causal relationship between the drug and this clinical finding has not been established.

There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert. Convulsive seizures have also been reported. A definite causal relationship between Cylert and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with Cylert often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (white) in bottles of 100 (**NDC** 0074-6025-13)
37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)
75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

Cylert Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored)
in bottles of 100 (**NDC** 0074-6088-13)

WE'RE FIGHTING FOR YOUR LIFE

The best references you can own are Mosby books — See for yourself ...

A New Book
MASSACHUSETTS GENERAL HOSPITAL HANDBOOK OF GENERAL HOSPITAL PSYCHIATRY
Increase your understanding of the psychiatric symptoms that can — and often do — erupt in the physically-ill. This long-awaited book throughly examines the behavioral disorientation resulting from hospitalization, and analyzes the psychiatrist's role on the health team.
Noted authorities focus on both chronic and acute illnesses — chronic pain, accidents, spinal cord injuries, burns and renal disorders — and offer valuable suggestions you can use to prevent or alleviate trauma.
You'll be especially interested in the chapter, *Psychiatric Consultation for Treatment Decisions in Irreversible Illness*. It discusses ethical aspects, judging responsibility and outlines a protocol for formulating difficult decisions as well. Be among the first to benefit from the valuable insights in this innovative volume — reserve your copy now!
Edited by Thomas P. Hackett, M.D. and Ned H. Cassem, M.D.; with 22 contributors. November, 1978. 612 pages, 13 illustrations. **Price, $14.95.**

New 6th Edition. **A SYNOPSIS OF CONTEMPORARY PSYCHIATRY.** By George A. Ulett, M.D., Ph.D. and Kathleen Smith, M.D. Use the new edition of this popular synopsis to find a brief outline of any aspect of mental illness. References have been updated and integrated with pertinent areas of the text. Highlights include a new chapter on sleep disorders ... a new listing from the College of Psychiatry with classifications for mental retardation ... and a glossary that features new nomenclature and contemporary vocabulary. June, 1979. Approx. 384 pp. **About $14.50.**

A New Book. **THE CHILD AND DEATH.** Edited by Olle Jane Z. Sahler; with 29 contributors. You can more effectively counsel the parents and family of a dying child with the help of this timely new book. Sensitive and unique in its emphasis on children, it offers a multi-disciplinary approach to this difficult problem. Four sections describe and detail: child's development of the concept of death; social workers' experience with the dying child and family; caregivers' reaction to the fatally ill child; effects on survivors and religious, ethical and educational questions. December, 1978. 318 pp., 7 illus. **Price, $9.95.**

A New Book. **HEADACHE AND HEAD PAIN: Diagnosis and Treatment.** By Robert E. Ryan,Sr., M.S. (Otolaryngology), M.D., F.A.C.S. and Robert E. Ryan, Jr., M.D.; with 6 contributors. How many of your patients describe headache or head pain among their symptoms? This new reference can help you identify the myriad conditions that can cause head pain, including cranial neuralgias, psychogenic headache, headache of ophthalmic, dental and neurologic origin, and migraine. Each chapter suggests effective methods for treatment and management. October, 1978. 444 pp., 30 illus. **Price, $39.50.**

2nd Edition. **THE LANGUAGE OF MENTAL HEALTH.** By William E. Fann, M.D. and Charles E. Goshen, M.D. Carefully updated, this edition presents the most modern terminology of the five mental health fields: mental disorders; human behavior; treatment; administration and law; and related sciences. Two appendices encompass: slang, abbreviations, and colloquial English terms; and historical biographies — and a valuable index of terms is arranged according to individual chapter subjects. 1977. 175 pp. **Price, $9.50.**

The patient with clinically significant depression

He's getting better...

and ELAVIL®

(AMITRIPTYLINE HCl | MSD

is helping

Helping with symptom relief

ELAVIL usually relieves a broad range of symptoms associated with depression, including sleep disturbance, one of the most frequently observed in the "constellation of symptoms," and usually the first symptom to respond to therapy.

And, the anxiety-reducing sedative component extends the drug's clinical value when depression is accompanied by symptoms of anxiety. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol.

Helping with convenient dosage regimens

ELAVIL offers a variety of convenient dosage regimens. A once-daily bedtime regimen may be an effective prescribing option, particularly when taken by a depressed patient experiencing sleep disturbance. ELAVIL can also be prescribed in divided daily doses. Prescriptions should be written for the smallest amount feasible.

Providing a wide range of tablet strengths

ELAVIL offers six color-coded tablets, available in the following strengths: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg. And for special circumstances, an injectable form is available. Injection ELAVIL is supplied in 10-ml vials, 10 mg/ml.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

Elavil®

(AMITRIPTYLINE HCl | MSD)

helping relieve the symptoms of clinically significant depression

MSD
MERCK SHARP & DOHME

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

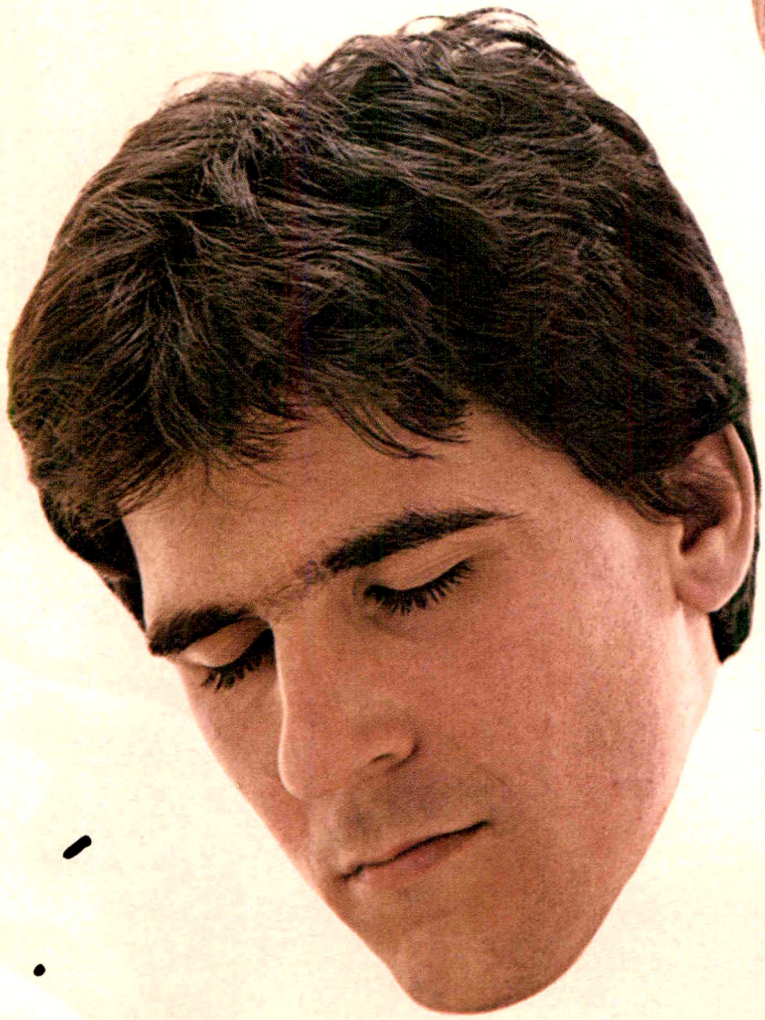
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486



J8EL26(116)

THE MANY FACES

Help for the apathetic/ withdrawn geriatric*

For the aged person suffering from withdrawn or apathetic senile behavior, Ritalin can often help relieve bothersome symptoms. In one double-blind study[1] of withdrawn, apathetic geriatric patients, Ritalin elicited notable improvement in competence, interest and retardation. While no side effects were reported in this study, blood pressure and pulse variations were noted in both groups but were not considered of exceptional magnitude.

Help for narcoleptic patients

The narcoleptic patient can fall asleep anytime...anyplace... and the consequences can be grave, or at the least, embarrassing. Although there is no known cure for narcolepsy, Ritalin acts promptly to counteract sleepiness and is the medication most frequently used by cited investigators.[2,3] Occasional problems of tolerance may be managed by complete withdrawal of Ritalin during vacation or holidays, then reinstating the drug at lower dosage.[3]

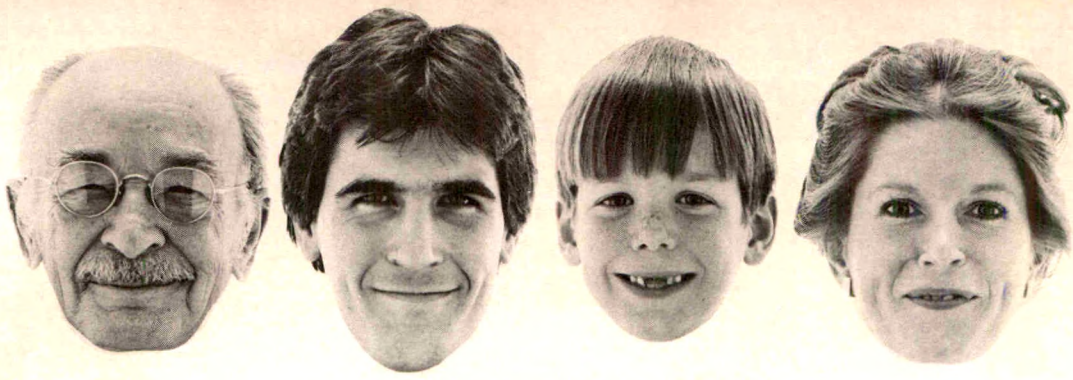
*Ritalin has been evaluated as possibly effective in these indications.

OF RITALIN® C II

(methylphenidate)

Help for patients with mild depression*

As Ritalin acts promptly to relieve symptoms of mild depression, mood and outlook usually improve, and the patient can cope again. Generally, one prescription is sufficient. Ritalin is contraindicated in severe depression.



Help for the MBD child

For the child with Minimal Brain Dysfunction (MBD), adjunctive Ritalin is often highly effective when medication is needed to help reduce symptoms such as distractibility,[4] disorganized behavior,[4] and hyperactivity.[4] MBD children responding to Ritalin usually exhibit better classroom performance and improved interpersonal relationships. Moreover, as MBD symptoms are curbed, the affected child often responds more positively to nonpharmacologic modalities.[5] Ritalin should be periodically discontinued to assess the child's condition. Improvement may be sustained when the drug is temporarily or permanently discontinued.

Please turn page for prescribing information.

RITALIN® C
(methylphenidate)
SO MUCH HELP FOR SO MANY PATIENTS

Ritalin® hydrochloride C
(methylphenidate hydrochloride USP)

TABLETS

INDICATIONS
Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indications as follows:
Effective: Minimal Brain Dysfunction in Children—as adjunctive therapy to other remedial measures (psychological, educational, social)
Special Diagnostic Considerations
Specific etiology of Minimal Brain Dysfunction (MBD) is unknown, and there is no single diagnostic test. Adequate diagnosis requires the use not only of medical but of special psychological, educational, and social resources.
Characteristics commonly reported include: chronic history of short attention span, distractibility, emotional lability, impulsivity, and moderate to severe hyperactivity; minor neurological signs and abnormal EEG. Learning may or may not be impaired. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.
Drug treatment is not indicated for all children with MBD. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.
Appropriate educational placement is essential and psychosocial intervention is generally necessary. When remedial measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms.
Effective: Narcolepsy
"Possibly" effective: Mild Depression; Apathetic or Withdrawn Senile Behavior
Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS
Marked anxiety, tension, and agitation are contraindications to Ritalin, since the drug may aggravate these symptoms. Ritalin is contraindicated also in patients known to be hypersensitive to the drug and in patients with glaucoma.

WARNINGS
Ritalin should not be used in children under six years, since safety and efficacy in this age group have not been established.
Sufficient data on safety and efficacy of long-term use of Ritalin in children with minimal brain dysfunction are not yet available. Although a causal relationship has not been established, suppression of growth (ie, weight gain, and/or height) has been reported with the long-term use of stimulants in children. Therefore, patients requiring long-term therapy should be carefully monitored.
Ritalin should not be used for severe depression of either exogenous or endogenous origin.
Ritalin should not be used for the prevention or treatment of normal fatigue states.
There is some clinical evidence that Ritalin may lower the convulsive threshold in patients with prior history of seizures, with prior EEG abnormalities in absence of seizures, and, very rarely, in absence of history of seizures and no prior EEG evidence of seizures. Safe concomitant use of anticonvulsants and Ritalin has not been established. In the presence of seizures, the drug should be discontinued.
Use cautiously in patients with hypertension. Blood pressure should be monitored at appropriate intervals in all patients taking Ritalin, especially those with hypertension.
Symptoms of visual disturbances have been encountered in rare cases. Difficulties with accommodation and blurring of vision have been reported.

Drug Interactions
Ritalin may decrease the hypotensive effect of guanethidine. Use cautiously with pressor agents and MAO inhibitors.
Human pharmacologic studies have shown that Ritalin may inhibit the metabolism of coumarin anticoagulants, anticonvulsants (phenobarbital, diphenylhydantoin, primidone), phenylbutazone, and tricyclic antidepressants (imipramine, desipramine). Downward dosage adjustments of these drugs may be required when given concomitantly with Ritalin.

Usage in Pregnancy
Adequate animal reproduction studies to establish safe use of Ritalin during pregnancy have not been conducted. Therefore, until more information is available, Ritalin should not be prescribed for women of childbearing age unless, in the opinion of the physician, the potential benefits outweigh the possible risks.

Drug Dependence
Ritalin should be given cautiously to emotionally unstable patients, such as those with a history of drug dependence or alcoholism, because such patients may increase dosage on their own initiative.
Chronically abusive use can lead to marked tolerance and psychic dependence with varying degrees of abnormal behavior. Frank psychotic episodes can occur, especially with parenteral abuse. Careful supervision is required during drug withdrawal, since severe depression as well as the effects of chronic overactivity can be unmasked. Long-term follow-up may be required because of the patient's basic personality disturbances.

PRECAUTIONS
Patients with an element of agitation may react adversely; discontinue therapy if necessary.
Periodic CBC, differential, and platelet counts are advised during prolonged therapy.

ADVERSE REACTIONS
Nervousness and insomnia are the most common adverse reactions but are usually controlled by reducing dosage and omitting the drug in the afternoon or evening. Other reactions include hypersensitivity (including skin rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis, and thrombocytopenic purpura); anorexia; nausea; dizziness; palpitations; headache; dyskinesia; drowsiness; blood pressure and pulse changes, both up and down; tachycardia; angina; cardiac arrhythmia; abdominal pain; weight loss during prolonged therapy. Toxic psychosis has been report
Although a definite causal relationship has not be established, the following have been reported in tients taking this drug: leukopenia and/or anemia few instances of scalp hair loss.
In children, loss of appetite, abdominal pain, wei loss during prolonged therapy, insomnia, and tachycardia may occur more frequently; however any of the other adverse reactions listed above n also occur.

DOSAGE AND ADMINISTRATION
Adults
Administer orally in divided doses 2 or 3 times da preferably 30 to 45 minutes before meals. Dosag will depend upon indication and individual response.
Average dosage is 20 to 30 mg daily. Some patie may require 40 to 60 mg daily. In others, 10 to 15 daily will be adequate. Patients who are unable t sleep if medication is taken late in the day should take the last dose before 6 p.m.

Children with Minimal Brain Dysfunction
(6 years and over)
Start with small doses (*eg*, 5 mg before breakfas and lunch) with gradual increments of 5 to 10 mg weekly. Daily dosage above 60 mg is not recommended. If improvement is not observed after appropriate dosage adjustment over a one-mont period, the drug should be discontinued.
If paradoxical aggravation of symptoms or other verse effects occur, reduce dosage, or, if necess discontinue the drug.
Ritalin should be periodically discontinued to as the child s condition. Improvement may be sustained when the drug is either temporarily or per nently discontinued.
Drug treatment should not and need not be indef and usually may be discontinued after puberty.

HOW SUPPLIED
Tablets, 20 mg (peach, scored): bottles of 100 ar 1000.
Tablets, 10 mg (pale green, scored): bottles of 1(500, 1000 and Accu-Pak® blister units of 100.
Tablets, 5 mg (pale yellow): bottles of 100, 500 ar 1000.

GENERAL HOSPITAL PSYCHIATRY

Psychiatry, Medicine and Primary Care

Editor-in-Chief:
D. R. Lipsitt, Chief of Psychiatry, Mount Auburn Hospital, Cambridge, MA

Aims and Scope:
General Hospital Psychiatry explores the linkages and interfaces between **Psychiatry, Medicine and Primary Care.** The Journal emphasizes a biopsychosocial approach to illness and health, and provides a forum for communication among professionals with clinical, academic and research interests in psychiatry's essential function in "the mainstream of medicine." Building upon those liaison-consultation and psychiatric services which have burgeoned in the general hospital setting, the Journal expands beyond this base to encourage new contributions to the understanding and treatment of illness-in in-patient, ambulatory, and community settings. Studies of multi-system relationships of life stresses, physical experience, psychosocial factors, interpersonal and intrapsychic reactions, family structure, ecological change, and institutional forces are especially relevant to the Journal's objectives.

Subscription Information: Volume 1 (4 issues) 1979
$60.00 institutional rate including postage and handling
$30.00 personal rate including postage and handling
Individuals must send remittance with their orders. Subscribers outside of the U.S.A. should add the following amounts: surface mail: $4.00, air mail to Europe and Canada: $10.00, air mail to the rest of the world: $16.00

Elsevier North Holland will feature General Hospital Psychiatry along with other outstanding medical and scientific books and journals at the American Psychiatric Association Meeting.

Please write to the publisher for a sample copy.

In moderate depression and anxiety

Only Limbitrol relieves this range of symptoms this rapidly.

And without a phenothiazine.

Limbitrol is indicated for the treatment of patients with moderate to severe depression associated with moderate to severe anxiety.

The therapeutic response to Limbitrol occurs earlier and with fewer treatment failures than when either amitriptyline or chlordiazepoxide is used alone.

Symptoms likely to respond in the first week of treatment include: insomnia, feelings of guilt or worthlessness, agitation, psychic and somatic anxiety, suicidal ideation and anorexia.

Limbitrol.
Dual therapy with greater specificity...without classical phenothiazine drawbacks.

ROCHE

ecommendations for treatment are biased
xperience with its components. Primary
ould be with the dangers associated with
e overdosage. Deaths by deliberate or acci-
erdosage have occurred with this class of

ents suspected of having an overdosage of
rol should be admitted to a hospital as soon as
able.
nifestations: High doses may cause drowsiness
mporary confusion, disturbed concentration or tran-
ient visual hallucinations. Overdosage may cause
hypothermia, tachycardia and other arrhythmias, ECG
evidence of impaired conduction (such as bundle
branch block), congestive heart failure, hypotension,
convulsions, severe hypotension, stupor and coma.
Other symptoms may be agitation, hyperactive reflexes,
muscle rigidity, vomiting, hyperpyrexia or any of those
listed under Adverse Reactions.
Treatment: Empty the stomach as quickly as possible by
emesis or lavage. In the comatose patient a cuff
endotracheal tube should be placed in position prior to
either of these measures. The instillation of activated
charcoal into the stomach also should be considered. If
the patient is stuporous but responds to stimuli, only
essential maintenance may be required. It
close observation and nursing care may be required. If
an adequate airway and fluid in-
take. Body temperature should be watched closely and
appropriate measures taken should deviations
occur.
The intramuscular or slow intravenous administration of
1 to 3 mg in adults (or 0.5 mg in children) of physo-
stigmine salicylate (Antilirium®) has been reported to
reverse the manifestations of amitriptyline overdosage.
Because of its relatively short half-life, additional doses
may be needed at intervals of 30 minutes to 2 hours.
Convulsions may be treated by the use of an inhalation
anesthetic rather than the use of barbiturates. Cardiac
monitoring is advisable, and the cautious use of digitalis
or other antiarrhythmic agents should be considered if
serious cardiovascular abnormalities occur. Serum
potassium levels should be monitored and kept within
normal limits by the use of appropriate I.V. fluids. Plasma ex-
panders and corticosteroids may be used to control
circulatory shock.
Dialysis is unlikely to be of value, as it has not proven
useful in overdosages of either amitriptyline or chlor-
diazepoxide. Since many suicidal attempts involve mul-
tiple drugs including barbiturates, the possibility of
dialysis being beneficial for removal of other drugs
should not be overlooked.
Treatment should be continued for at least 48 hours,
along with cardiac monitoring in patients who do not
respond to therapy promptly. Since relapses are fre-
quent, patients should be hospitalized until their condi-
tions remain stable without physostigmine for at least 24
hours.
Since overdosage is often deliberate, patients may
attempt suicide by other means during the recovery
phase.

amitriptyline intoxication by physostigmine. *JAMA*
230:1433-1434, Dec 9, 1974.

Dosage and Administration: Optimum dosage varies
with the severity of the symptoms and the response of
the individual patient. When a satisfactory response is
obtained, dosage should be reduced to the smallest
amount needed to maintain the remission. The larger
portion of the total daily dose may be taken at bedtime.
In some patients, a single dose at bedtime may be
sufficient. In general, lower dosages are recommended
for elderly patients.
Limbitrol 10-25 is recommended in an initial dosage of
three or four tablets daily in divided doses; this may be
increased to six tablets daily as required. Some patients
respond to smaller doses and can be maintained on two
tablets daily.
Limbitrol 5-12.5 in an initial dosage of three or four tablets
daily in divided doses may be satisfactory in patients
who do not tolerate higher doses.
How Supplied: White, film-coated tablets, each con-
taining 10 mg chlordiazepoxide and 25 mg amitriptyline
(as the hydrochloride salt) and blue, film-coated tablets,
each containing 5 mg chlordiazepoxide and 12.5 mg
amitriptyline (as the hydrochloride salt)—bottles of 100
and 500; Tel-E-Dose® packages of 100. Prescription
Paks of 50.

Please see summary of product information on last page of this advertisement.

LIMBITROL® TABLETS Tranquilizer—Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.

Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants: Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.

Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

Usage in Pregnancy: **Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).

Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.

In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.

Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.

This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:

Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.

Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.

Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.

Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.

Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.

Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.

Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.

Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single *h.s.* dose may suffice for some patients. Lower dosages are recommended for the elderly.

Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.

Supplied: Limbitrol 10-25 tablets each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and Limbitrol 5-12.5 tablets each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose* packages of 100; Prescription Paks of 50.

How to initiate and maintain therapy

Select dosage strength appropriate for each patient

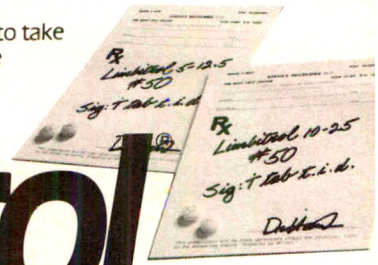
☐ Limbitrol 10-25 is recommended for most patients

☐ Limbitrol 5-12.5 may be indicated for those who do not tolerate higher doses and for elderly patients

Specify daily dosage based on symptom severity

☐ An initial dosage of three tablets is recommended.

☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary.



☐ Once a satisfactory response is obtained, evaluate response and, if necessary, reduce dosage to smallest amount needed.

Utilize dosage options to best accommodate individual patient needs

☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness

☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia

☐ Entire dosage h.s. to take maximum advantage of the sedative effect

Limbitrol

Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)

CIV

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.

2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.

3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted or the symptom treated.

4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.

5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.

6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:

1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Should not be given with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

a consideration beyond efficacy alone...

Infrequent akathisia and other disabling extrapyramidal effects...

The rapidly rising readmission rate among discharged psychotic patients is mainly due to noncompliance with antipsychotic drug therapy. And this, in turn, may be largely attributed to disabling extrapyramidal side effects, notably akathisia.[1]

Although extrapyramidal effects are characteristic of antipsychotic agents in general, with Mellaril (thioridazine) such effects are infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided. Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

Extrapyramidal Effects of Selected Antipsychotic Agents*[2]

DRUG	EXTRAPYRAMIDAL EFFECTS
Chlorpromazine	Moderate
Perphenazine	High
Prochlorperazine	High
Fluphenazine	High
Acetophenazine	Moderate
Trifluoperazine	High
Chlorprothixene	Moderate
Thiothixene	Moderate
Haloperidol	High
MELLARIL® (thioridazine)	Low

*Based on antipsychotic dosage ranges

Mellaril® (thioridazine)

ABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

ELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml: thioridazine se equivalent to 100 mg thioridazine HCl, USP

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

SANDOZ

SANDOZ PHARMACEUTICALS, EAST HANOVER, NEW JERSEY 07936 SDZ 9-319

Infrequent akathisia and other disabling extrapyramidal effects...

a consideration beyond efficacy alone for the discharged patient who needs an antipsychotic agent

Mellaril® [thioridazine]

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

MELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml:
thioridazine base equivalent to 100 mg thioridazine HCl, USP

THE AMERICAN JOURNAL OF PSYCHIATRY

Platelet Monoamine Oxidase Activity in Schizophrenia: A Review of the Data

BY RICHARD JED WYATT, M.D., STEVEN G. POTKIN, M.D., AND DENNIS L. MURPHY, M.D.

The authors review studies of platelet and white cell monoamine oxidase (MAO) activity in schizophrenic patients. The data on acute schizophrenic patients remain inconclusive. Review of 26 reports of chronic schizophrenic patients leaves little doubt, however, that there is a subgroup in which the enzyme activity is decreased. Despite the strong association of decreased MAO activity and chronic schizophrenia, the etiological relationship of low platelet MAO activity to schizophrenia has not been demonstrated. More complete diagnostic descriptions will shed light on precisely which patients have lowered MAO activity. Further metabolic investigations with such patients are needed to determine the physiological significance of this phenomenon.

AT LEAST 26 STUDIES have been published concerning the enzyme monoamine oxidase (MAO) in blood platelets and white cells of chronic schizophrenic patients (1-37) (see table 1). Although at times the deviation from control subjects has been very small, in all but 4 instances (22, 23, 33, 35) a decrease in MAO activity has been found. In 19 studies the reported decrease was statistically significant. Using the sign test, the chance of 22 of 26 studies demonstrating a decrease is less than 1 in 4,000, and the possibility of 19 of 26 being statistically significant at the .05 level by chance alone is less than 1 in 10^{19} (binomial test). In spite of this evidence, the finding continues to be thought of as controversial. We believe that what is controversial about the finding is not whether or not platelet MAO activity is decreased in some schizophrenic patients, but to what degree, in which patients, and what, if any, biological significance this decrease might have.

Received June 5, 1978; accepted Oct. 17, 1978; revised Jan. 9, 1979.

White Bldg., Rm. 536, St. Elizabeths Hospital, Washington, D.C. 20032. Dr. Murphy is Chief, Clinical Neuropharmacology Branch, National Institute of Mental Health, Bethesda, Md.

DEGREE OF DECREASE

The magnitude of the decrease in MAO activity in schizophrenia is important because profound alterations are usually demonstrated in diseases in which enzyme deficiencies have been found to be causative. Although the extent of the difference in platelet MAO between schizophrenic patients and normal subjects has varied from study to study, no study has reported a mean reduction greater than 68% from the MAO activity of normal control subjects (6). Group means, however, obscure individual differences, and in several of the studies some of the schizophrenic patients were found to have extremely low MAO activity. If these platelet alterations were shown to be systemic, they would be consistent with enzyme deficits found in many other genetic diseases. It should be noted that some genetically based disorders like porphyria may be associated with only partial enzyme reductions (on the order of 50% or less)—and that in other genetic disorders a wide variation of measured enzyme activity changes may be associated with various forms of the disorders (38).

Nevertheless, marked deficits in MAO activity are not characteristic of most schizophrenic patients; they occur in normal subjects as well as in individuals with other psychiatric diagnoses. In fact, great variability exists among the studies of schizophrenic patients.

SOURCES OF VARIABILITY

There are many potential sources of variability in studies comparing patients and control subjects. The

history of schizophrenia research indicates that schizophrenic patients in most studies have larger inter- and intra-subject variability than control subjects and other patient populations (39). We expect that the use of rigorous and standardized descriptive criteria across studies would decrease this variability.

Acute Versus Chronic Schizophrenia

Despite the lack of consensus among schizophrenia researchers as to which patients are diagnosed as acute and which as chronic, this separation does decrease variability (40). Since much more variability in platelet MAO activity has been found in studies of acute than of chronic patients, separating patients by clinical course is essential (see tables 1 and 2). It has also been suggested that separating acute (1–7, 24, 35 40–44) and chronic schizophrenic patients s essential in psychophysiological studies (45).

[a]When possible, we have made an attempt to distinguish discrete investigations. Each numbered study refers to a separate and unique group of patients investigated, but each may include several publications.
[b]The MAO activities of the schizophrenic patients are expressed as percentages of the MAO activities of the control subjects.
[c]Differences were not statistically significant.
[d]Used multiple substrates.

Control Groups

Selection of the control group is important. Berger and associates (31) noted that certain medical and professional hospital research personnel had unusually low MAO activity compared with nonprofessional hospital employees and college students (7.93 versus 11.17 nmol product per 10^8 platelets per hour). Professional hospital personnel are likely candidates for inclusion in control groups. In addition, Murphy and associates (46) and Buchsbaum and associates (47) found that college student volunteers with low platelet MAO activity had evidence of more psychopathology and had histories of more psychiatric and psychological counseling than students with higher platelet MAO activity. There was an increased risk of suicide in the families of male college students with lower platelet MAO activity. Subjects with low MAO activity have been described as being stimulus-seekers—people highly attuned to seeking out sensations from their environment (32). It is possible that students with low platelet MAO activity might be more likely to volunteer to be research subjects.

In addition to careful selection and description of both patient and control groups, factors such as sex of the subjects, age, administration of drugs, severity of illness, hormonal status, and dietary intake have been thought to be of potential significance. The sex of the subjects probably plays a role in platelet MAO activity: female subjects have been found to have a somewhat higher platelet MAO activity than male subjects (48, 49). Sex of the subjects has not always been taken into consideration in studies comparing control subjects with schizophrenic patients.

Age

The effect of age on MAO activity is disputed (48, 50), although there appears to be no correlation between the two in the age range in which schizophrenic patients are usually studied (20 to 50 years of age) (49). Nevertheless, in a study that did not find a statistically significant difference between chronic schizophrenic patients and control subjects (19), age of the patients could have been a factor. The age of the schizophrenic patients was 56.6 years, versus 47.9 years for the control subjects. If MAO activity increases after 50 years of age, studying older schizophrenic patients, especially if they are older than the control subjects, may alter the study's conclusions.

Drug Status

Several authors have suggested that drug status might contribute to the low levels of MAO activity seen in patients. Tricyclic antidepressants have been reported to inhibit MAO activity (51, 52). Becker and Shaskan (5) studied the clinical effects of tricyclic antidepressants in depressed schizophrenic patients and noted a decrease in MAO over time in 8 chronic schizophrenic patients who had high MAO activity. In view of the action of the tricyclics on MAO activity, it is possible that the decrease in MAO over time in some of these patients could have been due to the addition of tricyclics. However, the drugs most commonly used to treat schizophrenia, the phenothiazines and butyro-

phenones, have, if anything, a tendency to increase MAO activity (10, 13, 18).

Severity of Illness

Severity of illness may also be an important factor with regard to platelet MAO. Becker and Shaskan (5) found an inverse relationship between platelet MAO and severity of illness and symptoms, something we have also noted (2). However, Becker and Shaskan found no difference between combined schizophrenic inpatients and outpatients and normal control subjects, although borderline significant differences (χ^2=3.11, two-tailed, p=.078) exist between normal control subjects and inpatients at baseline. This latter finding was not reported because inpatients and outpatients were not originally examined separately in their publication.

Hormones and Diet

Hormones and nutrition are known to affect MAO activity (53, 54). The highest MAO activity in normal adult female human (55) and nonhuman primates (56) occurs just before ovulation; the lowest activity occurs in the postovulatory period. Estrogen is known to decrease MAO activity (57, 58). In severe iron-deficiency anemia, platelet MAO is markedly reduced, and this can be reversed by iron treatment (54).

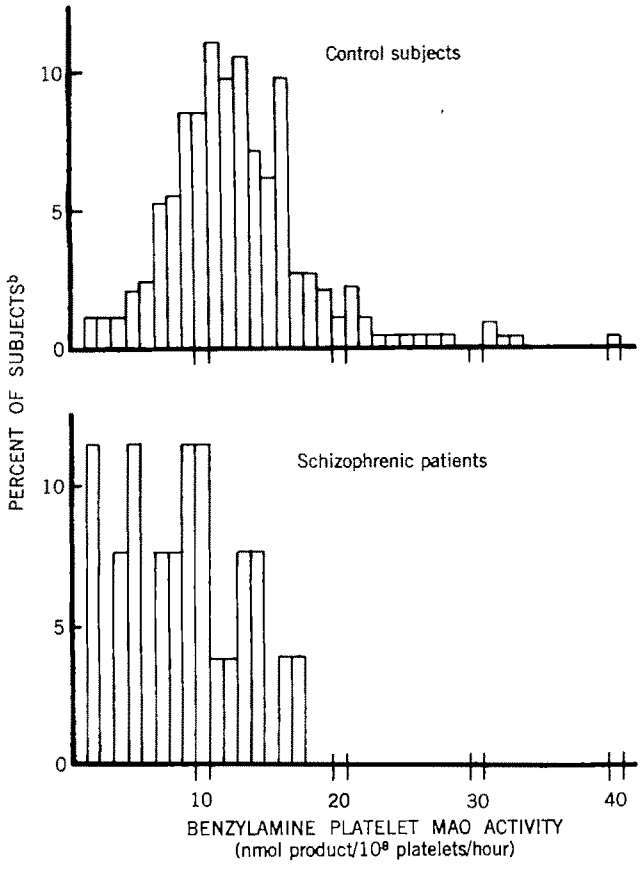
To examine hormonal and nutritional issues in relation to the observed decreases in MAO activity in chronic male schizophrenic patients, a group of 21 male chronic schizophrenic patients were studied (59). The mean serum triiodothyronine of these patients was in the middle of the normal range, but 2 of the patients had slightly elevated concentrations. The mean serum testosterone was in the lower portion of the normal range; 3 of the patients had concentrations less than 300 ng/ml. The mean serum iron concentrations, iron-binding capacity, and calculated mean percent saturation were near the middle of the normal range. None of these parameters had a correlation coefficient that even approached statistical significance. Thus, the hormonal and nutritional factors studied so far do not seem to play an important role in the decreased MAO activity found in these male schizophrenic patients.

Assay Procedure

Other sources of important variance can come from the assay itself. One problem with many biochemical assays is that their reliability in the lower range is poor—at times, the only thing that is measured is noise. Thus, when an assay is insensitive to low values, it is unable to make distinctions between those values. This would decrease any statistical significance that might occur between groups. Few of the papers on platelet MAO have addressed this problem. In the assay we are currently using (49), the values remain linear, even for subjects with low activity.

Preparation of platelets themselves can produce problems. Depending on how the platelets are separated, there may be a difference in platelet size and, perhaps, in MAO activity (35, 60). Differences in MAO activity in normal control subjects have been found when methods of platelet preparation are varied. No differences between control and schizophrenic groups were found by Friedhoff and associates (35) when high-speed centrifugation was used. Higher speed centrifugation tends to exclude the heavier platelets, which have the most MAO activity (60). However, Friedhoff and associates also found significant differences between control subjects and schizophrenic patients when platelets were harvested by lower-speed centrifugation, which yields more complete platelet recovery. The MAO increase for control subjects was 41% for benzylamine when the higher yield procedure was used (p<.01, two-tailed t test); no change was seen in the schizophrenic groups. Unfortunately, the second schizophrenic group was receiving neuroleptics, and the effect of drugs on platelet distribution and size has not yet been studied.

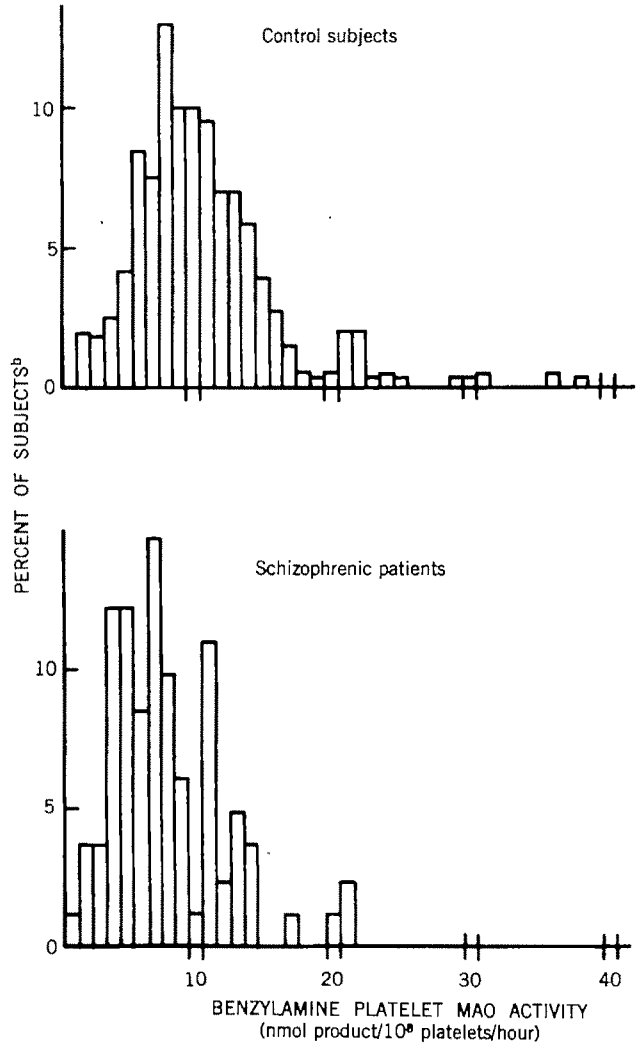
TABLE 3
Control Subjects' Mean Platelet MAO Activity with Tryptamine as Substrate in 12 Studies



Reference	Number of Subjects	MAO Activity (nmol/hr/mg protein)
Murphy and Wyatt, 1972 (1)	22	6.35
Wyatt and associates, 1973 (2)	23	6.4
Nies and associates, 1974 (42)	12	3.6
Friedman and associates, 1974 (41)	23	1.91
Meltzer and Stahl, 1974 (6)	15	5.24
White and associates, 1976 (21)	12	2.0
Domino and Khanna, 1976 (20)	13	7.14
Owen and associates, 1976 (9)	70	3.6
Berrettini and associates, 1978 (26)	10	3.7
Demisch and associates, 1977 (30)	42	2.0
Schildkraut and associates, 1978 (61)	28	5.72
Friedhoff and associates, 1978 (35)	37	8.46

Although the reasons for differences in the assays are not always apparent, we can readily see that they exist. Table 3 shows that, using the same substrate and somewhat similar assay procedures, platelet MAO activity in normal subjects varied from a low of 1.91 to a high of 8.46 in different studies. Although some of this variation could well be due to subject differences, the majority of it is probably due to differences in the preparation of platelets or assay procedures.

Statistical Issues



One type of statistical issue has already been addressed—that of not taking into consideration all the known sources of variance. Another statistical issue arises when there appears to be an obvious but not understood source of variance. Such a case may have occurred in the study reported by Brockington and associates (10). They presented data for control subjects and schizophrenic patients and found no significant differences. The mean MAO activity with tyramine as a substrate for their 70 control subjects was 28.4; for their 56 chronic schizophrenic patients it was 27.5. Al-

FIGURE 1
Frequency Distribution for Platelet MAO Activity in 332 Female Control Subjects and 26 Female Chronic Schizophrenic Patients[a]

[a]The mean level of MAO activity of the control subjects was 13.29±.29; the mean level of the schizophrenic patients was 8.44±.90. The difference between the group means was significant by two-tailed t test ($p<.001$).
[b]Bounded by one unit of MAO activity.

FIGURE 2
Frequency Distribution for Platelet MAO Activity in 348 Male Control Subjects and 122 Male Chronic Schizophrenic Patients[a]

[a]The mean level of MAO activity of the control subjects was 11.04±.29; the mean level of the schizophrenic patients was 7.04±.46. The difference between the group means was significant by two-tailed t test ($p<.001$).
[b]Bounded by one unit of MAO activity.

though these means are essentially identical, the histogram in their report shows that 8 of the schizophrenic patients had lower MAO activities than any of the control subjects. This suggests that there may be a subgroup of schizophrenic patients with low MAO activity who were not revealed in a comparison of group means. The observation that 8 schizophrenic patients had lower MAO activity than any of the control subjects is statistically significant at the $p=.01$ level (Fisher exact probability test).

Another source of variance lies in the distribution of subgroups of schizophrenic patients from population to population. Patient populations from different hospitals may not have the same distributions of subgroups of schizophrenic patients. If low platelet MAO occurred primarily in some of these subgroups, then, solely on the basis of selection, all studies would not be expected to demonstrate differences in platelet MAO. In all probability, schizophrenia, like pneumonia and mental retardation, is a number of diseases. If different investigators examine very different groups (e.g., process versus reactive, paranoid versus nonparanoid), they might be expected to find differences in etiological or associative factors. These potentially important differences become confounding factors when they are not explicitly separated in the experimental design.

MAO in Schizophrenia (NIMH Studies)

Figures 1 and 2 are frequency histograms of our sizable group of control subjects and chronic schizophrenic patients. For both male and female chronic schizophrenic patients (those whose onset was largely insidious and who have been hospitalized for more than 2 years), there was a marked mean decrease in platelet MAO activity in comparison with the control groups.

Delineation of Subgroups

In our initial studies of both acute and chronic schizophrenic patients (1, 2) we did not find any subgroup that had low MAO activity compared with other subgroups. Subsequently, we noted that the acute schizophrenic patients as a group were not different from control subjects (40). Among the acute patients, however, those with impaired reality testing, less restlessness, better prognostic scores, and paranoid and grandiose delusions tended to have lower MAO activity than other patients (15). Although most other studies of acute schizophrenic patients have not found this subgroup to have lower MAO activity, Schildkraut and associates (19) found in a mixed group of schizophrenic patients that those identified by the presence of auditory hallucinations had lower platelet MAO activity than others. The schizophrenic group with low platelet MAO activity was referred to as paranoid on the basis of the persecutory and accusatory nature of their delusions and hallucinations.

We have undertaken additional studies to look at the relationship of platelet MAO and subgroups of schizophrenia. The first (36) was a retrospective chart study in which many psychological and physiological parameters were correlated with platelet MAO activity. Low platelet MAO activity correlated with the presence of seizures and abnormal EEGs. Low MAO was also significantly more apparent in paranoid than in nonparanoid schizophrenic patients. A prospective study that eliminated patients with a history of seizures or abnormal EEGs and subgrouped patients on the basis of a prospective interview as well as a historical review (32) confirmed the association of low MAO activity with the paranoid subgroup.

A third study done in collaboration with investigators at the Palo Alto Veterans Administration Hospital in California (31) was unable to demonstrate a difference between paranoid and nonparanoid schizophrenic patients when subtyping was by chart diagnosis. Why one group of paranoid schizophrenic patients should be different from another is unclear. However, there is one likely difference between patients in a Veterans Administration hospital and those in St. Elizabeths Hospital. The patients at the Veterans Administration hospital were sufficiently intact at one time to have been inducted into military service and were functional for long enough to have gained veterans' benefits. The patients at St. Elizabeths Hospital may have had an earlier onset of their illness and may have been more process than reactive. Studies measuring these parameters will have to be carried out with both groups of patients. However, a recent report by Sullivan and associates (28), who also studied patients at a Veterans Administration hospital, found a difference between paranoid and nonparanoid schizophrenic patients. This finding suggests that the answer will be harder to determine.

To date, the clinically descriptive variables that have best distinguished paranoid from nonparanoid schizophrenic patients by a linear discriminant function analysis are, in order of importance, degree of suspiciousness, preoccupation with and systematization of delusions, delusions of control, stereotyped behavior, and intact memory (32).

Other investigators have attempted to subdivide patients in other ways. For example, Brockington and associates (10) found no difference in MAO activity between schizophrenic patients with positive symptoms (thought disorder, hallucinations, or delusions) and those with negative symptoms (flattening of affect, mutism). Brockington and associates also studied a group of schizo-affective patients and found that they had higher platelet MAO activity than the schizophrenic or control subjects. Elevated platelet MAO activity has also been reported in a group of patients described as having schizophrenia-related depressive disorders (61).

BIOLOGICAL SIGNIFICANCE

Is the Enzyme Different in Schizophrenia?

Initial observation (15, 62) suggested that the physical properties of MAO in schizophrenic patients and control subjects was not different. A number of lines of evidence are beginning to suggest that this may not be the case. Zeller and associates (7) reported a differential inability of platelets of schizophrenic patients to metabolize paraiodobenzylamine compared with tyramine and metaiodobenzylamine. Furthermore, subgroups of schizophrenic patients studied by Demisch and associates (30) appeared to have a differential lowering in their platelet MAO activity depending on the substrate examined. The paranoid subgroups had the lowest activities. In addition, lower Kms (Michaelis affinity constants) in schizophrenic patients have been found by Berrettini and associates (26). However, Belmaker and associates (23) found high Kms in schizophrenic patients, but their values, which were calculated from amphetamine inhibition curves for normal subjects, were 13-fold lower than our values at similar pH and substrates (19). Further studies are needed to determine if the physical and chemical differences in platelet MAO activity of schizophrenic patients are real.

Genetic Control

Several studies have indicated that platelet MAO activity in man is at least in part under genetic control. Normal (63) and affectively disordered (64) monozygotic twins have a much higher correlation of enzyme activity than do dizygotic twins or siblings. Monozygotic twins discordant for schizophrenia (2, 16) also have a high correlation of platelet MAO activity, as do first-degree relatives of schizophrenic patients who have high and low platelet MAO activity (16).

Low Platelet MAO Activity in Nonschizophrenic Groups

Low platelet MAO activity has been described in a number of groups of people. As previously stated, male college students with the lowest MAO activity (46, 47) had a high frequency of psychiatric counseling, more convictions for legal offenses, and increased suicides and suicide attempts in relatives. Alcoholics (65, 66), heavy users of marijuana (67), and bipolar depressed patients (68) also have been reported to have some decrease in platelet MAO activity.

It is tempting to speculate what these groups might have in common psychologically. Before any psychological commonality across disorders can be pursued very far, however, we need to know more than we do about the biochemical commonality. We know with varying degrees of certainty that these groups have reduced platelet MAO activity, but we do not know if MAO activity is reduced for the same reasons.

Cause or Association?

The decreased peripheral MAO activity seen in some schizophrenic patients could be related to the cause of the illness or could simply be associated with the disorder. A causal relationship would be particularly exciting because of the many biogenic amine hypotheses of schizophrenia. The dopamine (69), transmethylation (70), phenylethylamine (71), and norepinephrine hypotheses would be consistent with a decrease in MAO activity. However, only an association has been established to date—i.e., low platelet MAO activity accompanies certain forms of schizophrenia.

MAO activity has been studied in the brains of schizophrenic patients who have come to autopsy. In all but one of the studies (15), brain MAO activity of schizophrenic patients has been no different from that of control subjects. As yet, no attempt has been made to subgroup the schizophrenic patients (e.g., paranoid versus nonparanoid) whose brains have been studied. Studies of tissues other than blood components and brain have not been completed. There is one negative study comparing fibroblasts in schizophrenic patients and control subjects. However, fibroblasts predominantly contain a different form of MAO than the platelet and lymphocyte (33).

Presuming that peripheral tissues other than the platelet and white cells are involved, but not the brain, can the decrease in MAO activity in those tissues be causative? We believe that it could be, but there is no evidence thus far that it is. An example of how this might take place is readily at hand. Phenylketonuria, a disorder whose principal symptoms and signs are derived from altered brain function, is not primarily a brain disorder, but one of the liver. The enzyme phenylalanine hydroxylase, which converts phenylalanine to tyrosine, is deficient in the liver (little or none is normally present in the brain), and abnormally high metabolites cross from the blood into the brain, disrupting normal function.

A similar phenomenon could occur in schizophrenia. For example, of the known endogenous substrates for platelet MAO, phenylethylamine (PEA) has the greatest affinity for the enzyme. PEA is structurally similar to amphetamine (α-methyl-PEA) and produces many analogous behavioral phenomena in animals (72, 73). PEA readily crosses the blood-brain barrier, and if it were elevated in schizophrenia it might be expected to produce a psychosis similar to that produced by amphetamine. Of the 3 published studies of urinary PEA in schizophrenic patients (74–76), however, only 1 (74) suggested that PEA might be elevated.

If decreased MAO activity is causative in schizophrenia, why does inhibition of MAO by drugs not produce a psychosis? In fact, although MAO inhibitors are used as antidepressants, their use can be accompanied by significant behavioral toxicity, including some prominent stimulant effects in some individuals (77). However, most patients treated with MAO-inhibiting drugs do not develop any behavioral toxicity and certainly do not develop schizophrenia. Several possible explanations for this paradox deserve exploration. Since schizophrenia is primarily a disorder beginning shortly after puberty, data regarding short-term therapeutic inhibition of MAO in the adult may not be relevant to the still-developing adolescent brain.

Alternatively, perhaps simply having decreased MAO activity is not enough to produce disease at any time; perhaps other genetic disorders or environmental factors are needed. There is a body of literature, for example, suggesting that a higher proportion of schizophrenic patients are heterozygotes for phenylketonuria than would be expected in the general population (71). Could two genetic abnormalities (having low MAO and being a heterozygote for phenylketonuria) that are relatively innocuous when found by themselves produce a major disorder when they are found together in the same person? Alternatively, ameliorative factors may be present in most people but missing in others (78).

CONCLUSIONS

We believe there is an association between low platelet MAO activity and some forms of schizophrenia. The physiological significance of this finding is very much open to question insofar as this abnormality has been found in other populations and no alteration in amine metabolism has been found in association with low MAO. Certainly we need better diagnostic descriptions of the patients with the abnormality so that more meaningful comparisons can be made across study populations.

Delirium After Cataract Surgery: Review and Two Cases

BY WILLIAM K. SUMMERS, M.D., AND THEODORE C. REICH, M.D.

The authors define the delirium seen after cataract surgery on the basis of Dupuytren's original description and review studies using the criteria they set up on this basis. They then present prospective data on 2 patients with postcataractectomy delirium and 25 patients who did not experience this delirium. The data suggest that delirium after cataract surgery represents anticholinergic toxicity.

CLEAR DEFINITION of criteria is necessary for accuracy of diagnosis, especially with respect to psychiatric diagnosis (1). The many studies on psychiatric phenomena after cataract surgery are often conflicting and vague because of a lack of diagnostic criteria.

In this study, we will use a definition of the delirium seen after cataract surgery that is consistent with Dupuytren's original description (2). Specifically, postcataractectomy delirium refers to an acute change in a patient's mental status after cataract surgery and requires the presence of disorientation *and* disturbance of recent or remote memory as well as the presence of two or more of the following six symptoms: delusions, hallucinations, illusions, depersonalization, change in affect (anxiety, fear, depression, or euphoria), and abnormal psychomotor activity.

LITERATURE REVIEW

Using these criteria, we found that several studies of postcataractectomy delirium had inadequate data for interpretation of case reports (3–20). Table 1 gives the reported incidence, age, sex, time of onset of delirium, and duration of the delirium in 20 published studies (2, 21–39) as well as in the one reported here. Excluding the highest and lowest, the range of incidence represented in these studies is .3% to 15.9%. The zero incidence reported by Burns (27) is questionable because his patients had surgery at home, were not followed up until a week after surgery, and apparently were not specifically asked about delirium. Questioning is important because patients tend not to report these episodes spontaneously (38, 40, 41) However, Burns noted "several" episodes of delirium in his hospitalized cases. The 62% incidence reported by Linn and associates (35) was in a selected population with a 72% incidence of chronic organic brain syndrome.

The mean age range of patients with postcataractectomy delirium shown in table 1 was 50 to 85. The mean number of days after surgery that delirium occurred in the 85 patients in whom onset was observed was 3.1 days. Analysis of usable data shows that 82.5% of the cases of delirium occurred before the third postoperative day. As in most acute organic brain syndromes, the course of the delirium was noted to wax and wane (1, 26, 28, 29, 32, 33).

The duration of delirium after cataract surgery is either acute or chronic (34). The acute course has been reported to have a duration of minutes to more than 16 days. A chronic course has been reported in a small number of individuals (8, 28, 34). Table 1 shows the range of duration of delirium in 68 patients. The average number of days an acute course lasted was 2.6 days. Return to preoperative mental status by the fourth day after onset of delirium occurred in 87% of these cases.

Predisposing or causal factors in postcataractectomy delirium cited in 19 published studies (2, 21–26, 28–39) and in the one reported here are listed in table 2. Previous psychiatric illness, especially chronic organic brain syndrome and alcoholism, have often been mentioned (10, 17, 21, 28, 31, 33). There is evidence for an association of preoperative chronic organic brain syndrome and postcataractectomy delirium (25, 42). Association between the delirium and alcoholism or other psychiatric disease is unclear for lack of data in a comparison population (28, 34). Data on the association of the delirium and uremia (14, 18) also lack information on control subjects. The theory that sensory deprivation from bilateral patching is causative is interesting but unproven (3, 7, 11, 12, 37, 41, 43–45) (see table 3). Several authors (3, 10, 17, 22, 23) have reported the delirium in the absence of bilateral eye patching. In addition, the removal of the patch from the unoperated eye often does not result in rapid reversal of the delirium (22, 26, 31, 32, 33, 35). Analysis of the literature for response to removal of a patch from the unoperated eye indicates an immediate improvement in only 9 of 47 cases (19.1%). There are no reports evaluating orientation or memory testing after removal of patch-

Received March 28, 1977; revised Oct. 11, 1977; accepted Dec. 19, 1977.

es. The term "improvement" seems to mean that a patient was less agitated.

The following investigation is a pilot prospective study of psychiatric symptoms after cataract surgery, using psychiatric research criteria (1).

METHOD

Thirty-three subjects undergoing intracapsular cataract extraction at Barnes Hospital in St. Louis, Missouri, were asked to participate in this investigation.

[a]Improvement within 1–2 hours after removal of bilateral patches.
[b]Improvement more than 2 hours after removal of bilateral patches.

After the study procedure had been explained to these patients, as required by the hospital's Human Usage Committee, 27 patients agreed to participate. Each subject was interviewed a minimum of four times. The presurgery interview included a medical-surgical history and a psychiatric history (1). Memory was tested using the "names-learning test" of Irving and associates (46). A mental status examination and the memory testing was done within 12 hours of surgery and again 48–72 hours after surgery. A fourth interview was conducted either by telephone or in person between 7 and 10 days after surgery. Laboratory values, nursing observations, and medications were obtained from the patients' charts.

The patients who had had no diagnosable episode of postcataractectomy delirium 7 days after surgery were considered our control group.

All of the subjects were given the names-learning test (46). A score of less than 44 of a possible 60 was considered indicative of a disturbance of recent memory. Patients who had had conditions requiring daily medications and/or medical surveillance at least every 3 months before their cataractectomy were considered as having a previous medical diagnosis.

A numerical system devised to estimate the patients' exposure to delirium-inducing agents during a given 24-hour period was calculated by multiplying the class number of the drug (described below) by the daily effective dosage level number (also described below). The result was termed the "drug risk number." Criteria for the class number of drugs were as follows: class 1=known synergistic effect with anticholinergic agents but not known to be a direct cause of delirium; class 2=known to cause delirium but currently not known to have CNS anticholinergic properties; and class 3=known to cause delirium reversible by physostigmine (i.e., known to cause an acute anticholinergic syndrome). The criteria for daily effective dosage level numbers were as follows: dosage level 1=dose range that would not have therapeutic effect for a 24-hour period; dosage level 2=dose range that would have therapeutic effect for a 24-hour period; and dosage level 3=dose range that exceeds the usual therapeutic range. All of the dose ranges were verified using standard pharmacological sources (47, 48).

As an example of the numerical system, a patient receiving 50 mg of secobarbital h.s. as his or her only charted medication would have a drug risk number of 3. Secobarbital is a class 3 drug but would typically require 200 mg per day to achieve therapeutic effect (i.e., sleep) over a 24-hour period. The total drug risk number for a 24-hour period was calculated as the sum of the drug risk numbers for each agent used in the same 24-hour period.

RESULTS

Two of the 27 patients (7.4%) developed postcataractectomy delirium.

Case Reports

Case 1. Ms. A, a 76-year-old married woman, had a 6-month history of decreasing visual activity and had been admitted for bilateral intracapsular cataract extraction. Her medical history revealed mild glaucoma that did not require medication, occasional "forgetfulness," and a cholecystectomy with an uneventful postoperative course. There was no family history of neuropsychiatric illness. Initial examination revealed a visual activity of 20/400 in both eyes with no evidence of glaucoma. She was well oriented and showed no evidence of memory impairment.

On the second hospital day the patient underwent a right intracapsular cataract extraction with local anesthesia of 2% lidocaine (Xylocaine) with epinephrine and hyaluronidase (Wydase). Light cautery was required for a "slight amount of bleeding." The postoperative course was uneventful mentally and physically. On the fifth hospital day the patient underwent a left intracapsular cataract extraction with the same anesthesia and no complication. At 8:00 p.m. on the seventh hospital day (36 hours after surgery) the patient became confused. She thought she was at home cleaning her house and was disoriented to time. Only the more recently operated eye was patched, and her room was well lighted. The next morning she continued to be disoriented and scored only 14 of a possible 60 on the names-learning test. Anticholinergic agents were withheld. Her mental status continued to wax and wane with mood swings, delusions ("someone is going to bury me alive"), and auditory and visual hallucinations ("of knights and princesses").

Physical examination showed mydriasis of the right pupil, a regular pulse of 96, temperature of 37°C, and slightly dry skin. There were no focal neurological signs. Her BUN was 24 mg/100 ml, creatinine was 1.4 mg/100 ml, fasting blood sugar was 101 mg/100 ml, serum calcium was 9.8 mg/100 ml, serum phosphorus was 2.9 mg/100 ml, alkaline phosphatase was 79 mU/ml, and serum glutamic-oxaloacetic transaminase was 38 mU/ml. Urinalysis, complete blood count, serum electrolytes, skull X ray, EEG, ECG, and brain scan showed no significant abnormality.

Twenty-four hours after the onset of delirium, 1.5 mg of physostigmine was given slowly I.V. with ECG monitor to rule out acute anticholinergic syndrome (49, 50). Before infusion the patient was disoriented to time, place, and person. She admitted that she had visual hallucinations. Her affect was consistent with fear, and she scored only 1 on the names-learning test. Testing done 15–30 minutes after physostigmine administration revealed recognition of family members, minimal disorientation to time (Ms. A stated the date of her operation), and a score of 46 on the names-learning test. However, the physostigmine trial was marred by gastrointestinal side effects. Two hours after physostigmine infusion the patient was again grossly disoriented. She gradually improved over the next 10 days. A computerized tomography scan was read as showing slight enlargement of the lateral ventricles and cerebral atrophy. On the 16th hospital day the patient was consistently oriented and scored 50 on the names-learning test. Follow-up interview revealed no further difficulties with memory or orientation and no hallucinations.

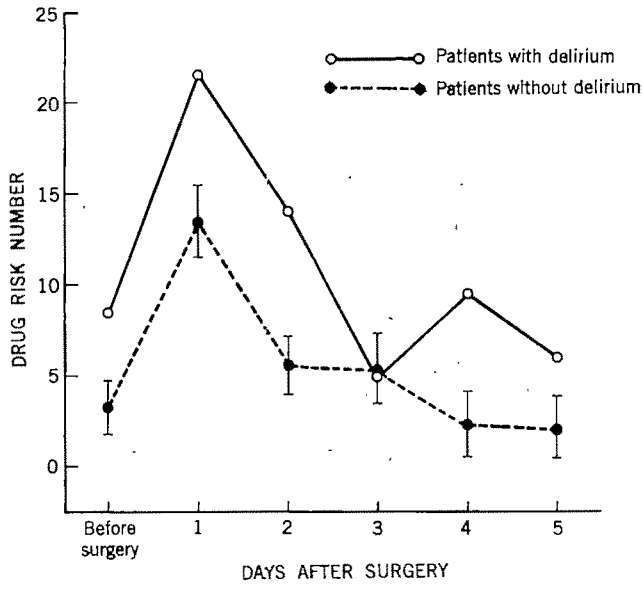
Case 2. Ms. B, an 82-year-old widow with bilateral cataracts, had noted decreasing visual activity for 8 months. Her history revealed mild hypertension for 15 years requiring various medications for 6 years and a left cerebral vascular accident with nearly total recovery 2 years before this admission. She and her family denied any psychiatric or surgical history. A granddaughter noted that the patient occasionally forgot where she put items but had not observed any gross disorientation. On admission the patient was taking 40 mg of furosemide (Lasix) o.d. and .15 mg of digoxin o.d. Physical examination showed mild obesity with grade ii/vi systolic ejection murmurs and S_4 gallop. Ocular examination revealed a visual activity of 20/200 on the right and 20/400 on the left, with no increase in intraocular pressure. The patient was oriented and her initial names-learning test score was 54.

On the second hospital day Ms. B underwent a right intracapsular cataract extraction under local anesthesia, as described in case 1, without complication. Twenty-six hours after surgery, at 9:00 a.m., the patient was observed sitting on a stool picking at imagined bugs and giggling. The most recent medications she had received were 200 mg of secobarbital the night before the operation; 50 mg of I.M. diphenhydramine (Benadryl), 10 mg of I.M. prochlorperazine (Compazine), and three drops of 1% Cyclogyl in the right eye at the time of the operation; and 1% atrophine twice since the operation. The operated eye had been examined about 1 hour before the episode. Physical examination 45 minutes after the beginning of the episode revealed a temperature of 37.2°C, a pulse of 100, and slightly moist skin. The patient's right eye was patched, and her left pupil was mydriatic. Mental status examination revealed a change of affect from euphoric to tearful within minutes. The patient was hyperactive, picking at her arms while giggling and saying, "This is wonderful." She admitted that she saw unusual things but refused further comment. There was gross disorientation to time, but the patient knew which hospital she was in and recalled her surgery. She recalled one of three objects after five minutes but could not recall her home address. Her names-learning test score was 10.

On repeat mental status examination 3 hours after the onset of the episode the patient was normal. She recalled that "it was like a dream. I saw different things coming by, people, the girl next door, and other things."

Anticholinergic agents and sedatives were withdrawn, and the patient had no further episodes. On the eighth hospital day she underwent a left intracapsular cataract extraction without subsequent delirium.

Comparison Group



Twenty-five of the 27 subjects in this study did not have psychiatric sequelae to cataract removal. The mean age of these control subjects was 71.9±11.1 years (range, 54–96). The mean age of the control subjects is similar to that reported for patients with postcataractectomy delirium (see table 1). Twenty-two of the control subjects were white, and 3 were black; 17 were women, and 8 were men; 9 had had previous psychiatric illnesses; 1 had had a previous postcataractectomy delirium; and 8 had a positive family history of psychiatric disorders.

Table 2 allows comparison of the data for our control subjects and those for patients with delirium reported in the literature. Two of the control subjects (8%) were suspected of alcohol abuse, compared with a mean of 22.7% of the 66 patients with delirium for whom such data were available in the literature. None of the control subjects was suspected of having chronic organic brain syndrome, compared with 33.3% of 63 delirium patients in the literature. Fourteen (56%) of the control patients, however, were suspected of having some other form of psychiatric illness, compared with 13% of 23 delirium patients. Five (20%) control subjects experienced some postsurgical complication, compared with 16% of 81 delirium patients. Three (12%) control patients had a preoperative medical diagnosis of renal disease, compared with 13.6% of 59 delirium patients. Finally, 19 (76%) control patients had some other preoperative medical diagnosis, compared with 8.5% of 47 delirium patients.

Comparison of preoperative laboratory results for patients who did or did not experience postcataractectomy delirium in the literature was not possible. Comparison of our laboratory data by t test (one-tailed) showed that the 2 patients who experienced delirium had significantly elevated BUN and creatinine levels ($p<.001$). Similar comparisons were not significant for hematocrit, white blood cell count, serum sodium, serum potassium, serum bicarbonate, serum glutamic-oxaloacetic transaminase, lactic dehydrogenase, bilirubin, alkaline phosphatase, serum calcium, and creatine phosphokinase.

Exposure to psychoactive drugs was measured by drug risk number values; these are displayed in figure 1. The mean drug risk number of patients who experienced delirium was greater than the mean plus the

SEM (1.96) drug risk number of the control subjects for the preoperative period and for postoperative days 1, 2, 4, and 5.

DISCUSSION

The occurrence of 2 cases of postcataractectomy delirium in 27 subjects in this series does not allow reliable statistical comparison. Nevertheless, there are several points of interest. The 7.4% incidence of delirium in this series is consistent with the incidence in the literature. The mean age (71.9±11.1 years) and age range (54–96) of our control subjects was not remarkably different from those of delirium patients noted in the literature (see table 1).

The theory that delirium is associated with older age (8, 11, 21) appears unlikely. When comparison was possible, no significant differences were found between our control subjects and our patients with delirium or those in the literature for race, sex, previous psychiatric illness, previous medical disease, family history of psychiatric disorder, or postoperative eye complications. Thus, the suggested association of delirium with poor general health (4, 21, 22, 26) or with any previous psychiatric illness (3, 11, 17, 33) is not supported by our findings. (The only patient with chronic organic brain syndrome in this series developed postcataractectomy delirium. This is not mathematically consistent with the 72.2% frequency of delirium in patients with chronic organic mental syndrome found by Linn and associates [35].)

The apparently significant decrease in renal function of the 2 patients with delirium in our study was unexpected. This finding was reinforced by a slight elevation in BUN and creatinine in another patient with postcataractectomy delirium who was not part of this study. It would appear that the hypothesis of renal autotoxicity advanced by Fromaget in 1900 [6] merits further investigation.

The bilateral patching or sensory deprivation hypothesis appears improbable on the basis of the literature (see table 3). Both of the patients in our series who developed delirium had experienced no apparent sensory deprivation.

Our results suggest that postcataractectomy delirium may be an acute anticholinergic syndrome. The clinical presentation and course of the two syndromes is similar (51). This similarity was noted as early as 1910 (52). It is known that mydriatic agents can induce delirium at therapeutic doses (53, 54), and Dameshek and Feinsilver (55) demonstrated that mydriatic delirium was caused by anticholinergic toxicity. Further, the 2 patients with delirium in our series received greater exposure to all psychoactive agents (see figure 1). Janowsky and associates (50) postulated that such agents may act synergistically to produce acute anticholinergic syndromes.

Most impressive was the rapid clearance of delirium in 1 of our patients for 2 hours after administration of physostigmine. It has been suggested that rapid improvement after physostigmine constitutes proof that a patient had an acute anticholinergic syndrome (49, 50). There are several explanations for the cholinergic gastrointestinal side effects precipitated by physostigmine in this patient. Most probably, the dose of physostigmine was excessive for the degree of anticholinergic intoxication. It seems likely that this patient had anticholinergic intoxication. It seems unlikely that the delirium would have spontaneously cleared for a period consistent with the known duration of action of physostigmine. In short, it seems unlikely that the physostigmine was totally unopposed by exogenous anticholinergic substances.

Finally, the patient may have had isolated CNS toxicity. Here it may be postulated that the mydriatic agents would have access to the vitreous because of the disruption in the usual ocular physiology in which the drug would be taken up by the neurons and transported by anterograde axonal transport into the CNS (56). This would result in isolated CNS anticholinergic toxicity. Given these circumstances physostigmine would cause clearing of CNS anticholinergic toxicity while precipitating peripheral cholinergic toxicity.

The etiology of delirium after cataract surgery remains unclear. This study suggests that the syndrome represents anticholinergic intoxication. Further work needs to be done to test this hypothesis; to clarify the association of postcataractectomy delirium to chronic organic brain syndromes; and to establish any relationship of postcataractectomy delirium to renal pathology.

Adult Mental Health Services in a Health Maintenance Organization

BY SIMON H. BUDMAN, PH.D., JUDITH FELDMAN, M.D., AND MICHAEL J. BENNETT, M.D.

The authors describe an adult mental health service within a health maintenance organization and present information on the department's setting, staffing patterns, programs, and philosophy. They believe that the emphasis on brief focal psychotherapy, the staff of mental health care providers who are committed to this type of setting, and the thorough integration of the program into the larger HMO system all contribute to the provision of high-quality services at a reasonable cost.

HEALTH MAINTENANCE ORGANIZATIONS (HMOs) are prepaid group practices characterized by integration of facilities, voluntary enrollment, and an emphasis on preventive services (1). Recent surveys indicate that 7 million Americans now belong to such plans and that this figure is increasing (2). At first, prepaid health plans provided mental health services only on a limited basis, usually through a special rider at extra cost. The federal HMO Act of 1973 (P.L. 93-222) (which requires that qualified HMOs must provide short-term outpatient mental health evaluation and treatment to all members) is contributing to an increase in the number of HMOs providing direct mental health services as a standard benefit.

In this article, we will describe an HMO mental health department that is heavily engaged in direct patient care. We will examine the nature of the setting, the professional staff, referral patterns, and treatment modalities and discuss some of the unique aspects of such a system.

THE SETTING

The Harvard Community Health Plan (HCHP) in Boston, Mass., was started in 1969. Until Jan. 1, 1977, HCHP had a contractual relationship with Massachusetts Blue Cross and 10 private insurance companies. This contractual relationship has been phased out, and the plan is now responsible for marketing, member services, billing, and premium collection. All plan physicians have teaching appointments at the Harvard Medical School, and medical patients are hospitalized mainly at Harvard teaching hospitals.

At present, the plan has two centers: the original Kenmore Center with 38,000 members, and the newer Cambridge Center with 31,000 members (only the former will be described in this paper). The Kenmore Center currently employs the full-time equivalent of 40 physicians and 32 nurses, who are organized by specialty into separate areas of one building.

The HCHP monthly premium is approximately 20% below that of a Blue Cross-Blue Shield Master Medical Policy. It covers all inpatient and outpatient services with a small copayment for each visit.

The majority of plan members are between the ages of 20 and 40 and subscribe to the plan through their place of employment. Because the plan is offered to an entire company or organization, members vary widely in income and occupation. Four percent of the population is indigent and their care is supported through a contract with the Massachusetts Welfare Department. Less than 1% of the population is enrolled under a special health cost supplementation program of the U.S. Public Health Service.

THE MENTAL HEALTH DEPARTMENT

The adult mental health department includes the full-time equivalent of 3 psychiatrists, 3 psychologists (Ph.D. level), 1 social worker (M.S.W. level) 2 psychiatric nurses (M.S. level), and one half-time alcoholism counselor. (There is also a fully staffed child psychiatry service, which will not be described here.) The average age of the staff is 38 and the average clinical experience 13 years.

Staff members are selected on the basis of sound psychodynamic training, interest and experience in working in a high-pressure medical setting, interest in a group practice, and commitment to problem-oriented short-term psychotherapy. Applicants are interviewed by several members of the mental health department and also by members of other departments within the plan. The psychiatrists and psychologists are members of the HCHP physicians group and are part of the same salary contract as the other plan physicians. Psychiatric nurses belong to planwide nursing groups and

Received Nov. 14, 1977; revised Jan. 20, 1978; accepted March 29, 1978.

committees. The department does not have a hierarchical structure: all staff members share equally in evaluations and treatment, regardless of discipline. Supervision within the department is mandatory for new clinicians for 6 months and optional thereafter. A full-time mental health staff member (40 hours a week) spends about 70% of his or her time doing clinical service. For part-time staff, this fraction is even higher. Staff time not spent in direct clinical service is used for consultation, administration, and staff meetings.

The mental health unit is located entirely within the Kenmore Center. Like other departments in the plan, it participates in the plan's automated record system and also maintains its own appointment system and operates within its own budget. In 1978 the mental health department had 20,000 outpatient visits, representing about 8% of total plan visits. A recent survey indicated that about 15% of the plan members who use health services use the mental health department at some time during their membership.

Before January 1976, when the Massachusetts Mental Health Law took effect, the plan excluded from coverage individuals with chronic or recurrent psychiatric illness and offered only brief therapy. HCHP is now legally obligated to offer the equivalent of $500/year of outpatient mental health service to all members. Rather than contracting out for the additional services, the department chose to expand its programs. Currently, 5% of the monthly premium is used for mental health benefits. The benefit structure provides 20 outpatient sessions per year at the copayment fee, which is usually $1. One hour of individual treatment or 1.5 hours of group treatment equals one visit. Additional visits are billed at the rate of $40 per session for individual treatment and $10–$20 per session for group treatment, depending on income. HCHP also provides 60 days of full hospitalization or 120 days of partial hospitalization (in a psychiatric hospital) and 30 days of inpatient alcohol or drug detoxification per year.

PRIMARY CARE AND MENTAL HEALTH SERVICES

When a family joins HCHP, each adult member chooses a physician/nurse primary care team from the internal medicine department. All subsequent medical visits (routine and emergency) are scheduled with that team. Other departments are generally used by the primary care team as consultant specialists. The triage (emergency) area, staffed by nurses with physician backup, provides care to new members who have not yet chosen a primary care team. It also provides off-hour coverage to all plan members.

At HCHP, mental health benefits are broad and available to all members, but mental health care is also seen as an essential function of the primary care team. In order to reconcile the expectations for specialized services with the commitment to a primary care model, the department has attempted to create and sustain a high level of awareness throughout the organization of the importance of social and psychological issues in medical care. Consequently, such issues are addressed throughout the system rather than being relegated to the mental health specialist.

Mental health professionals have conducted in-service presentations and seminars on medical-psychological issues for both primary care trainees and staff doctors and nurses. In addition, mental health staff meet regularly with primary care, obstetrics/gynecology, and surgical staff to review cases and problem issues. There are also several joint clinical programs, such as continuing care and a crisis group. The social worker in the mental health department consults in primary care areas and helps providers deal with social, emotional, and economic issues in their practices. Finally, physical contiguity allows for frequent informal discussions about shared patients and problems.

TREATMENT IN THE MENTAL HEALTH DEPARTMENT

After the primary provider completes a form stating the nature and urgency of the patient's problem, the patient is scheduled for an appointment on the basis of his or her extent of symptomatic distress and functional impairment. After the evaluation is completed, the therapist sends a note back to the referring provider with a diagnostic impression and recommendations for no treatment, referrral back to primary care, or treatment within the mental health department.

The predominant mode of treatment in the department is focused short-term individual or conjoint couples therapy (defined as 20 or fewer sessions, but usually fewer than 10). Another approach is the crisis group, run jointly by a mental health provider and a triage nurse, which meets twice a week for an hour and a half. The group has a rotating membership and leadership. Patients are referred during a life crisis (marital separation, death of relative, etc.) and may attend the group for up to 8 sessions. This group is focal, active, task-oriented, and very supportive. Initial data (3) indicate that patients have an overwhelmingly positive response to the group and often require no further treatment.

Based on the favorable follow-up data from the crisis group, there has been increasing work with short-term groups for selected problems. These groups are used to treat individuals and couples with developmental or life-stage issues and to provide a "corrective" social experience for those with focal interpersonal concerns (4, 5). In 1978 about 300 of the 1,300 new patients were seen in short-term group therapy. Some groups are open-ended and have rotating membership; others are closed groups and run for about 15 sessions. There is often an attempt to set up groups with fairly homogeneous membership (couples, young adults, persons dealing with mid-life issues, etc.).

Some staff members have specialized training and may treat patients with hypnosis, direct sexual therapy, etc. Such techniques may at times be used as an adjunct to other forms of therapy. Patients with chronic mental illness who require support, medication, and structure may be followed in several ways: by their primary care team, by a mental health provider (in widely spaced half-hour sessions), or in the continuing care program. This program (6) is run by the mental health department, with a nurse from internal medicine participating. A large, informal group meets twice a week, and patients may attend as often as they wish. The group functions to provide support and socialization. The leaders hold brief individual sessions with patients as needed to regulate medication. Patients are often referred after hospitalization in the hope that this follow-up may reduce the frequency or severity of recurrent illness.

In addition to the approaches described above, since January 1976, HCHP has provided long-term, open-ended individual or group treatment for those who need it (7). This program is very carefully monitored. A therapist referring a patient for long-term treatment writes an extensive evaluation, which must be approved by a committee of mental health department members. Patients continue with the referring therapist if he/she has time available (each staff member may carry up to 4 long-term individual treatment patients) or are assigned to another staff member. Cases are scheduled to be reviewed yearly. The criteria for referral were developed by an ad hoc committee of mental health department members after discussion within the entire group and emphasize the patient's need for extended treatment rather than simply his or her capacity to benefit from it. Although department staff initially feared they would be inundated by referrals, between Jan. 1, 1976, and Jan. 1, 1979, only 114 patients were referred for long-term therapy. We estimate this to be less than 2% of the patients seen during this period.

In the alcohol abuse program, a psychiatrist and an alcoholism counselor provide information and backup to primary providers. They conduct educational groups, see patients and families in consultation, and occasionally provide direct service—usually short-term treatment.

Staff members rotate emergency coverage on a weekly basis. A mental health provider is available 24 hours a day by portable pager for telephone consultation to the internist or triage nurse on call. The mental health provider may talk with the patient directly or arrange hospitalization when indicated. Time is also allotted during the working day for unscheduled patients who require immediate intervention.

Since HCHP does not have its own hospital, arrangements have been made to hospitalize plan patients at a nearby private psychiatric hospital. To be approved and covered, hospitalization must be arranged by a member of the mental health staff. The department has worked with the hospital to develop programs for partial hospitalization (overnight admissions and day care). A psychiatric nurse maintains daily contact with the hospital treatment team (not employed by HCHP) to help coordinate inpatient treatment and aftercare. In 1978, there were 43.4 hospital days per 1,000 members, representing 116 patients hospitalized, with an average length of stay of 14.1 days.

An individual patient may be involved at various times in several of the above treatment approaches and may return to a therapist for several courses of brief treatment. With most short-term approaches, it is assumed that the working through process continues after formal therapy ends. Brevity of treatment is enhanced by early access and by favorable patient and staff attitudes toward psychotherapy.

UNIQUE ASPECTS OF THE HCHP MENTAL HEALTH SYSTEM

Strupp and Hadley (8), in describing a conceptual model for evaluating psychotherapy outcome, propose that there are three "interested parties" in these evaluations: society, the individual, and the mental health professional. A tripartite model also fits well in understanding the unique demands of providing mental health services within this HMO system. At HCHP, the three interested parties are the institution itself, the patient, and the provider. Institutional demands are experienced by providers in an HMO much more strongly than they are in other mental health delivery systems. The treatment relationship in private practice can be insulated from institutional or societal demands. Even when an insurance company or the state is paying for treatment, the interests of those institutions often can be ignored or kept at a low priority by the clinician and patient. The HCHP system differs in that the plan is the insurance company. Clinicians wear three hats simultaneously: they represent the plan in allocating its finite mental health resources, they represent the patient's interest in "feeling better," and they represent their own perspective as clinicians with an interest in enhancing the patient's personality structure and coping style. The tension generated by these multiple perspectives is considerable.

Overtreating (allocating too much time to a patient) has direct institutional implications. In the short run, other patients may go without or have to wait for therapy. There may be added clinical demands placed on providers in mental health and other departments because of the backlog of patients awaiting treatment. In the long run, excessive waiting time may mean decreased consumer satisfaction and withdrawal from the plan or increased premiums in order to hire more therapists to treat patients for a longer period. Of course, in increasing premiums, the institution again risks losing members.

Undertreating (allocating too little time to a patient) has implications from all three perspectives: the un-

dertreated patient may 1) feel shortchanged and choose to quit HCHP, 2) seek emotional support elsewhere in this closed system, making excessive demands on other health care providers, or 3) return to the mental health department for additional treatment. Undertreatment also has major implications for the satisfaction of mental health practitioners. For clinicians with an understanding of psychodynamics and personality theory and a wish to be helpful to others, morale would plummet if it were felt that treatment was only superficial and temporary and did not influence the patient's coping and adaptational styles.

Thus mental health providers within the system must maintain multiple perspectives quite unlike the perspective(s) maintained by providers within other mental health systems. These multiple perspectives generate a dynamic tension in each provider, since providers exist within and are responsible to a peer group (the mental health group practice). This leads to a careful scrutiny of how mental health services are being allocated and a tendency toward problem-oriented psychotherapy.

It appears that the HCHP mental health department can treat most patients briefly without constantly undertreating because of the unique structure of the organization. A patient who finishes a course of psychotherapy does not leave the system. He or she maintains membership, continues to see his or her primary care providers as needed, and has ready access to the mental health department. The overall institution provides the patient with a supportive matrix of services that can take up where the psychotherapist leaves off.

THE FUTURE

The major challenge facing the mental health department is to provide total, high-quality care to a large population with varied needs and to keep costs at an acceptable level. The department is now moving in the direction of more group psychotherapy, better crisis and emergency treatment, preventive programs, and research and evaluation.

An NIMH-supported project on preventive mental health is studying the economic feasibility of providing plan members who have recently undergone marital separation with a program called "Seminars for the Separated" (9). This series of didactic and experiential meetings is aimed at lessening the trauma associated with marital separation.

There is an active concern within the department about education, scrutiny, and review. In an attempt to generate evaluative research, staff members meet weekly on an informal basis to examine the short-term group psychotherapy program. It is the goal of this research group, composed of interested staff members, to monitor services, evaluate outcome, and to help clarify the quality and cost-effectiveness of this program.

CONCLUSIONS

The experience of the mental health department at HCHP suggests that a complete range of mental health services can be provided in a cost-effective manner. The total cost of all services—adult and child, inpatient and outpatient—is approximately $2 per member per month.

The opposing tensions within this system necessitate an emphasis on brief, problem-oriented treatment. In order to make this approach work, the mental health department must be large enough to support a variety of programs and be fully integrated into the total health care system. Mental health providers must be committed to the concept of primary care and to the health plan as a whole.

A Behavioral Program for the Treatment of Chronic Patients

BY JOHN F. HOFMEISTER, M.D., ALBERT F. SCHECKENBACH, PH.D., AND SHIRLEY H. CLAYTON

The authors report the development of a short-term behavioral therapy program for chronically hospitalized schizophrenic patients who had responded only minimally in a therapeutic community. The basic program was a token economy, which concentrated on personal care activities, productive activities, and leisure activities, combined with drug treatment. During the first 9 months of the program 105 patients were admitted and 79 were discharged—24 to nursing or group homes and 47 to their own home or family. At 1-year follow-up 62 patients were still in the community without any readmissions. The findings that a token economy can be effective with chronic patients at comparatively little additional expense has broad implications for custodial care facilities with limited resources.

SINCE THE EARLY 1960s Fort Logan Mental Health Center has been a leader in the development of a therapeutic community. Maxwell Jones, a leading advocate of the concept of the therapeutic community, was first a visiting consultant and then resident consultant at Fort Logan. Under his guidance a strong program was developed that benefited a large number of Fort Logan patients (1) and significantly influenced the development of therapeutic programs throughout the world. However, Kraft and associates (1) found a hard-core group of patients at Fort Logan—primarily chronic schizophrenics—who were minimally responsive to milieu treatment.

Over the last 5 years the psychiatric inpatient population of Fort Logan has been shifting to an increasing percentage of chronic patients with severe deficits in interpersonal functioning. These patients were poorly equipped to involve themselves in the vigorous give-and-take of an active therapeutic community. They characteristically drifted to the periphery of the ward treatment program as passive observers. A few assumed a deviant role. Others became scapegoats of the community, e.g., the clown, the stupid one, the crazy one. Despite the staff's vigorous efforts to intervene in this destructive group dynamic, polarization of the patient subgroups hardened. These patients were often frightened by the staff's attempts to involve them. The staff experienced frustration in trying to draw them out. Active intervention with these patients showed a gradual but steady decrease. The patients themselves became frustrated and discouraged by their repeated failures. Their returns to the community became less frequent and of shorter duration. The length of their hospitalizations began to increase, and a number became chronically hospitalized.

The increasing length of hospitalization among these patients and their relatively poor treatment response had serious implications. Dunham and Weinberg (2) reported that length of hospitalization has been shown to be inversely correlated with the probability of release. Gurel (3) and Ullman (4) found that of patients hospitalized for 2 years, only about 6% are discharged. Chronic patients have extremely high rates of rehospitalization (5, 6). Van Putten (7) cited 8 studies to show that milieu therapy fails to produce significant improvement in chronic schizophrenic patients.

Staff concern for the chronic patients at Fort Logan prompted a search for an alternative treatment modality for them. In 1968 Ayllon and Azrin (8) reported on a behavioral program employing a token economy with long-term chronic patients at Anna State Hospital in Illinois. These patients had been hospitalized for an average of 16 years before the behavioral program began; almost all of them showed a significant improvement in work performance. Lloyd and Garlington (9) reported similar success in increasing the self-care behavior of chronic patients. Schaefer and Martin (10) worked to improve the apathetic behavior of chronic patients, with impressive results. Since then there have been a large number of studies employing behavioral programs with chronically hospitalized patients. The current literature has been reviewed by Hagen (11) and Stahl and Leitenberg (12).

The decision to set up a behavioral treatment unit at the Fort Logan center to treat the most severely disabled patients was made only after considerable discussion, evaluation, and a good deal of apprehension.

Received Sept. 28, 1977; revised Jan. 27, 1978; accepted March 29, 1978.

At the time this work was done the authors were with Fort Logan Mental Health Center, Denver, Colo., where Dr. Hofmeister was Division Psychiatrist, Dr. Scheckenbach was Consultant for Behavior Therapies, and Ms. Clayton is Mental Health Worker and Clinical Administrator. Dr. Hofmeister is now Clinical Director, Program for the Chronically Mentally Ill, Jefferson County Mental Health Center, Lakewood, Colo. Dr. Scheckenbach is Western Regional Administrator, Psychology Services, Federal Bureau of Prisons, Englewood, Colo. The entire program was scheduled for reevaluation at the end of 9 months. A group of the most severely disabled and chronic patients, with the longest inpatient stays, was targeted for special, continuing follow-up.

METHOD

The behavioral treatment unit was established in November 1975; it had a capacity for 20 inpatients. The treatment staff consisted of 1 clinical administrator, 1 psychiatrist, 1 half-time psychologist, 1 social worker, 7 nurses, 7 mental health workers, and 1 half-time activity therapist. An outside consultant was selected who had particular expertise in behavioral treatment modalities with chronic patients. He gave 6 seminars to the staff to teach them the basics of behavioral therapy and helped design the ward treatment program. Staff members were also provided with basic textbooks on behavioral therapy for readings and reference (8, 13–15).

Patient Profile

The patients selected during the first 9 months for the behavioral unit were those who were relatively refractory to the therapeutic community based on prior history of treatment. The sample consisted of male and female patients; the average patient was between the ages of 20 and 55 and either had never married or was no longer married. Each patient had had multiple prior psychiatric hospitalizations and had been diagnosed as schizophrenic during 2 or more hospitalizations. Each was admitted to Fort Logan Mental Health Center only after several failures in a number of outpatient programs. The patient's relationships with parents and siblings were either ruptured or severely strained; previous friends were estranged. The average patient had either never held a job or worked only sporadically; he or she was usually supported by public assistance or social services. This group of patients ranked highest on a Fort Logan scale measuring disruptive behavior; their average score was 74%, compared with 50%–60% for all of the other adult inpatients. Most of these patients had previous admissions to the therapeutic community at Fort Logan; a representative sample of 30 patients had prior goal attainment scores more than one standard deviation below the mean for the entire inpatient population. The targeted group of chronic patients (average prior inpatient stay=1,200 days) were treatment failures on the therapeutic community, manifested by a gradual decline in socially adaptive behavior, an increase in maladaptive behavior (e.g., violent temper tantrums, negativism, extreme isolation), and chronic hospitalization.

The Program

A multilevel system for performance and privileges was developed. Each level was designed to gradually shape behaviors needed for successful adjustment outside the hospital. All patients received the basic necessities of hospital life (i.e., food, bed, medical care) without having to earn them. Positive reinforcement (rewards) for adaptive behaviors was the basis of the program. Maladaptive behaviors were usually treated by extinction (ignoring the behavior). The basic program was a token economy in which patients earned points on a scale of performance for adaptive behaviors. Adaptive behaviors were defined as those useful for life outside the hospital. The points could later be exchanged for luxuries on the ward (i.e., cigarettes, extra coffee, candy, cosmetics). Extremely disabled patients who could not comprehend the token system received tangible items directly for adaptive behavior. Written contracts were established for less disabled and greatly improved patients. These contracts, which were drawn up in cooperation with the patients, enabled them to obtain special needs from the staff in exchange for adaptive behaviors. Patients moved from one level of the program to another as their needs and performance changed.

The token economy program concentrated on personal care activities, productive activities, and leisure activities. Instruction in basic skills was included in each activity program. Personal care activities included personal hygiene, oral care, use of toilet items, clothing, and room care. Used clothing, jewelry, games, cards, and so forth could be purchased with points in the hospital's used-clothing shop or by shopping trips to the community for those who had their own money. Basic toilet articles (e.g., deodorant, soap, shampoo) were provided free on request to each patient. Productive activities included an arts and crafts program, physical exercises and games, cooking and meal planning, sewing, and a sheltered workshop on the grounds. Patients who elected to work in the sheltered workshop received financial compensation that met or exceeded the minimum wage as well as points. Payment for all activities was scaled to performance, appropriate behavior, and on-time attendance. Leisure time activities included individual and group games, leisure planning, dancing, camping, bowling, trips, and swimming.

Whenever practicable, the scope of the program was expanded through the use of community services and facilities, e.g., vocational or job placement services, stores, swimming pools, museums. A halfway house on the hospital grounds was used to assist patients' transition to the community. Referral to a local mental health center was arranged prior to discharge to promote continuity of care.

The medium of payment for adaptive behaviors consisted of points stamped by the staff on each patient's card. This system was chosen to minimize the trading of points from one patient to another by maladaptive behaviors (i.e., threats, sexual favors, buying friends). Points were stamped in multiples of 10 and were cancelled by the staff with a paper punch when they were exchanged for goods or services. Staff attention

proved to be a very potent reinforcer and was directed toward patients engaged in adaptive behaviors. Points were given immediately after adaptive behaviors, coupled with an explanation of how the points were earned. At the same time social approval was presented consistent with the patient's level of achievement and capacity to perform the behavior. Patients' earnings in 19 separate categories were recorded each day by the treatment staff. Areas of strength or weakness and abrupt or gradual changes in performance could be readily assessed by a review of these records.

Treatment was individualized on admission by placing the patient at a level corresponding to his or her capacity to function, i.e., tangible reinforcer level, token economy level, or contract level. After a period of staff observation and review of the patient's recorded performance, special needs or problems were targeted for an individual operant program; these problems included eating with the hands, severe weight loss, neglect of self-care, wrist cutting, mutism, extreme isolation, and assaultiveness. Each patient's treatment program was reviewed weekly by the treatment team, and changes were made after review of the performance records, individual program records, and clinical observation.

Just as adaptive behavior resulted in positive reinforcement, extreme maladaptive behavior met with negative consequences. Most inappropriate behavior was ignored (extinction process). Extreme maladaptive behavior included assaultiveness, extreme agitation, serious destruction of state property, self-mutilation, serious threats, and elopement. These behaviors resulted in the patient's separation from staff and patients; the length of the separation depended on the patient's regaining control of his or her behavior. There was no overall system of negative consequences for the entire ward (e.g., fines), but negative consequences were employed in selected individual treatment plans. Restraints and/or seclusion for a specified time was used as a last resort to assist the patient in regaining control. Patients in restraints or seclusion were checked every 15 minutes by a staff member. The average time spent in seclusion or restraints was approximately 1 hour.

Each patient received a complete medical and neurological examination, including specialized studies when indicated. Antipsychotic and other psychoactive medications were used in accepted dosages (75–2000 mg of chlorpromazine or the equivalent dosage of another antipsychotic medication). In addition, megadoses of haloperidol (100–160 mg) were employed for several severely ill patients whose psychoses did not respond to usual doses of antipsychotic agents.

The program was evaluated after 9 months by the administration of a staff questionnaire and review of several objective measures that might be expected to correlate with effectiveness, i.e., length of hospitalization, recidivism rate, disposition of patients, property damage, sick leave used by the staff, and staff requests for transfer.

RESULTS

A total of 105 patients were admitted to the behavioral treatment unit during the first 9 months of operation, and 79 patients were discharged during this period. The average inpatient stay was 58 days. The chronicity and extreme disruption of interpersonal functioning in these patients led to a general expectation among hospital staff that a short-term treatment program averaging 6 weeks would achieve little more than a protective community placement, i.e., nursing home. In contrast to these expectations, only 24% of the discharged patients (N=19) were placed in nursing homes. Fifty-nine percent (N=47) were discharged to their own home, apartment, or family. Six percent (N=5) were discharged to a boarding home or lodge (work-oriented group home). Five percent (N=4) were discharged against medical advice. Four percent (N=3) transferred to other wards or hospitals. There was one death from a preexisting cardiac condition. Thirty percent of the patients (N=32) worked regularly in the industrial therapy workshop. With one exception, none of the patients was discharged to a behaviorally oriented day-care program (there was only one such program in the area at the time of this study).

The course of the discharged patients was reassessed one year after discharge. Excluding the deceased patient, 80% of the patients (N=62) were in the community without any readmissions. Twelve percent (N=9) were readmitted to Fort Logan with an average stay of 32 days; 2.5% (N=2) had 2 admissions with an average stay on each admission of 43 days; and 5.5% (N=4) had 3 readmissions with an average stay on each of 37 days. The one patient discharged to a behaviorally oriented day-care program was not readmitted.

The target population of long-term chronic schizophrenics (N=6) with an average prior inpatient stay at Fort Logan of 1,200 days was discharged within 9 months to less intensive treatment modalities, where the patients' average length of stay was 6 months. Follow-up 1 year after discharge showed that 1 patient was readmitted for 129 days; the others were in the community with no readmissions to Fort Logan.

During this study there were no suicides or serious self-inflicted injuries among the patients. Property damage on the ward was minimal (one broken window). There were two staff requests for transfer to other units. One staff member cited dislike of the behavioral treatment modality as a reason for requesting a transfer; the other cited difficulty working with chronic patients. Both staff members who transferred to other units subsequently left employment at Fort Logan. Staff turnover on the behavioral unit was the lowest among the adult psychiatric inpatient units at Fort Logan. Staff sick leave showed an abrupt rise during the first 2 months of the program to twice the hospital average (1.4 versus .746 days per employee per month). From the third to the ninth month of the program, the

sick leave of the behavioral unit staff remained at or below the hospital average. At 9 months the staff unanimously rated the behavioral program as effective; 61% rated it "extremely effective" and 39%, "moderately effective." The clinical status of the patients at discharge was evaluated by the attending psychiatrist; the mean rating was moderately improved.

DISCUSSION

This study indicates that a behavioral treatment program in combination with adequate diagnostic workup and drug treatment is effective in treating disabled chronic patients. This finding concurs with the results obtained by a number of other researchers. These studies have been reviewed by Stahl and Leitenberg (12). However, few studies have focused on the effect of short-term hospitalization with chronic patients. The results at Fort Logan Mental Health Center suggest that recently admitted patients with a severe chronic illness can improve sufficiently for discharge within 2 months (the average inpatient stay was 58 days). Patients with a long prior inpatient stay required a much longer period of hospitalization before they were ready for discharge. (The average inpatient stay was 6 months). The present practice at Fort Logan is to admit directly to the behavioral unit any adult patients with a severe psychotic illness associated with very low levels of performance and very poor interpersonal skills. In addition, adult patients on the therapeutic communities who fail to show significant progress within 6 weeks are regularly evaluated for transfer to the behavior modification unit.

The clinical impression at Fort Logan is that antipsychotic medications in adequate dosages work synergistically with a behavioral program for patients admitted in acute decompensation of chronic disease. However, this clinical impression has not been subjected to critical long-term evaluation.

The treatment staff has begun an evaluation of the posthospital adjustment of chronic patients treated on the behavioral ward. Preliminary findings are that a high level of performance in self-care activities, domestic skills, crafts, work, and other activities is not predictive of optimum posthospital adjustment. Of the high-point earners (600 points per day or more), those who are able to learn to form friendships and relate to others in a mutually satisfying manner have the best posthospital course. High-point earners who relate to peers by emotional exploitation (threats, manipulation, demeaning others), extreme submissiveness, or avoidance of peers combined with continued efforts to be a favorite of the staff show a much less adaptive course after hospitalization. The behavioral program at Fort Logan is now being revised to increase the emphasis on teaching and reinforcing interpersonal skills directed to appropriate conversation with others, helping others to do for themselves, cooperatively working with others, and cooperative leisure activities.

The cost of a behavioral program is another important consideration in these times of rapidly accelerating medical care costs. The cost of the behavioral treatment ward at Fort Logan is roughly equal to that of the center's therapeutic communities i.e., $100 per patient per day. The staff-to-patient ratio is 1:1, and the psychiatrist-patient ratio is 1:20. A custodial placement in the Denver area is far less expensive—$30 per day. However, costs are favorable if length of hospitalization is considered. The present cost for a 58-day course of treatment on the behavioral unit is $5,800; a year of custodial care in the Denver area costs approximately $10,900.

Preliminary indications in the literature are that a token economy can be implemented with comparatively little additional expense. This finding has broad implications for custodial care facilities with limited resources (e.g., nursing homes) that are seeking to upgrade the treatment of patients. Foster (16) analyzed the comparative costs of running a custodial ward and a token economy ward for 32 patients for 1 year and found that the cost of the token economy ward was $424 more than that of the custodial ward. Hagen (11) cited several successful behavioral programs that cost no more or little more to implement than traditional custodial care (up to $2.60 per patient per month). In addition, he found that several programs resulted in considerable savings for the institution in terms of decreased destruction of property, use of linens, and use of medications.

These findings have prompted the staff at Fort Logan to initiate an active behavioral consultation program with several nursing homes in the Denver area to assist them in developing token economies for their patients. The long-range goal is to provide long-term active behavioral treatment programs in the community for the 24% of our patients who do not respond to our short-term treatment program.

Early Review of Annual Meeting Papers

The *Journal* will continue this year its policy of early review of annual meeting papers. Final versions of papers that are ready before the Chicago meeting will be accepted for review. Do *not* submit your paper early if you anticipate substantive revisions after discussion at the meeting. Manuscripts should be submitted in triplicate, double-spaced throughout, and prepared in conformance with *Journal* style specifications, including length limitations. Papers written in "speech" format should not be submitted.

Please label the paper "Annual Meeting 1979, Final Version" and include on the title page the address and phone number of the corresponding author and the number of words, tables, and figures. The cover letter should incorporate the copyright transfer statement described in "Information for Contributors."

Since the *Journal* has first refusal rights for annual meeting papers, it is necessary to obtain the Editor's permission before submitting a paper elsewhere.

If your paper will not be ready for review before the meeting but will be in final form at that time, bring three copies to Chicago and submit them to the session Secretary (submitting copies to the Press Office *does not* satisfy this requirement). Again, papers that are not ready for review should not be given to the Secretary.

If you have questions about this or other *Journal* policies, please stop by the *American Journal of Psychiatry* staff office during the meeting, and staff members will be pleased to assist you.

The Impact of Normal Volunteers on a Psychiatric Research Unit

BY PHILIP GOLD, M.D., YOLANDE B. DAVENPORT, M.S.W., THOMAS WEHR, M.D., AND FREDERICK K. GOODWIN, M.D.

Normal subjects were admitted to a psychiatric unit devoted to the study and treatment of affective illness. Initially the authors were concerned about the difficulties volunteers might have living with psychiatric patients. However, the volunteers adjusted with relative ease, while the patients' depressive symptoms were exacerbated. Their confrontation with the volunteers' "normality" triggered an acute awareness of their underlying sense of failure. This response is analogous to depressed patients' reactions before discharge, when they struggle not only with their special vulnerability to separation and loss but with inevitable challenges to their fragile self-esteem during reintegration into the outside world. The presence of normal volunteers highlighted these issues and led to increased therapeutic work and considerable resolution.

IN CLINICAL PSYCHOBIOLOGICAL research it is essential that baseline data be obtained from normal subjects in a controlled setting. For over 20 years, "normal volunteers" have been hospitalized on most inpatient research units at the Clinical Center of the National Institutes of Health to provide control data for clinical projects. The psychiatric units were the only inpatient services that had not established the tradition of admitting normal volunteers. Counter to the strong local tradition, which was embedded in a vague fear of some unspoken risks, we admitted four college-age volunteers for a 3-month stay on a clinical research unit devoted to the study and treatment of affective disorder. Although a fairly extensive literature exists concerning issues of patient care on psychiatric research units (1-9), to our knowledge there have been no reports assessing the effects of resident normal control subjects on the life of a psychiatric research unit organized as a therapeutic milieu.

Received May 10, 1978; accepted Aug. 4, 1978.

Dr. Gold is Chief, Unit on Neuroendocrinology, Clinical Psychobiology Branch, National Institute of Mental Health, Bldg. 10, Rm. 4S239, 9000 Rockville Pike, Bethesda, Md. 20014, where Ms. Davenport is Chief, Unit on Family Studies, Dr. Wehr is Chief, Clinical Research Unit, and Dr. Goodwin is Branch Chief.

PATIENT CHARACTERISTICS AND SETTING

All patients were diagnosed as having major affective disorder by standard criteria (10, 11). The patients lived on a 12-bed research unit organized as a therapeutic community (12, 13) and participated in a variety of behavioral, biological, and pharmacologic studies that involved observer- and self-ratings, a controlled monoamine diet, blood samples, 24-hour urine collections, sleep studies, infusions, measurement of evoked potentials, lumbar punctures, and continuous monitoring of activity. In addition, each patient spent 2–3 hours a week in individual psychotherapy and 6 hours a week in group psychotherapy.

The volunteers participated in a similar regimen, but they did not undergo lumbar punctures, nor were their mood and behavior rated by the nursing staff. Moreover, they did not receive psychotherapy per se but met for 2 hours each week with a psychiatrist (P.G.) and for another hour each week with a social worker (Y.D.) to discuss their experiences on the unit. In addition, one of us (T.W.) had weekly contact with the patients and volunteers that focused on research participation. Like the patients, the volunteers' lives revolved around the unit, where they ate, slept, and spent much of their spare time, although they worked for several hours each weekday at a "career assignment" in a laboratory or other unit of their choice.

The material comprising this report was gathered from individual interviews, nurses' notes, and recordings of group meetings on the unit. The clinical observations were also the subject of regular group discussions among the authors.

EFFECTS OF THE NORMAL VOLUNTEERS ON THE PATIENT COMMUNITY

The response of the patient community to the normal volunteers will be described longitudinally in three separate phases: 1) the initial "activation" response, 2) the phase of depressive reaction, and 3) the partial identification and resolution of the depressive process. The duration of each phase was approximately 4 weeks.

Initial Response

The patients were given 3 weeks' advance notice that normal volunteers would be joining the milieu and

initially showed no signs of being affected by this announcement. However, the content of the next few group therapy sessions suggested that on a certain level the patients recognized that the volunteers would be, in effect, representatives of the "normal" community, raising the issue of the distinction between psychiatric patients and normal, healthy individuals. It was during one of these sessions that a patient who had been anticipating discharge with apparent confidence surprised the group by expressing doubts that he would be accepted as an equal in the normal outside world after having been hospitalized on a psychiatric unit. Other patients recalled similar predischarge fears during prior hospitalizations, fearing the reactions not only of their employers but of their friends and families. None of the patients related his or her current anxiety about returning to the community to the anticipated arrival of the college-age volunteers.

Other indirect evidence that the patients felt anxious about the volunteers surfaced in subsequent meetings. For instance, several patients requested that there be an increase in group and individual therapy hours, which suggested that they feared losing the sustained interest of the staff to the volunteers.

More direct acknowledgment of feelings concerning the volunteers took the form of anger at the administration for discriminating against patients by using the term "normal volunteer." This anger was elaborated in fantasies about scandalizing the young, innocent volunteers with feigned crazy behavior. One patient recalled a previous hospitalization for mania during which she had gotten on her hands and knees, barked, and chased a horrified visitor off the ward. The memory of her identification with an unruly animal provided a glimpse of her impoverished sense of self, derived in part from a past experience of uncontrolled behavior during manic episodes.

The patients seemed to divert many of the feelings accompanying such self-images into a variety of energy-consuming activities, such as making and then breaking alliances with the staff and among themselves or turning from one cause or project to another. In addition to serving a diversionary function, each of these maneuvers also seemed to protect the patients from a specific anxiety or feeling associated with the volunteers' anticipated arrival.

The next several days were characterized by the first of these maneuvers, an effort on the part of the entire patient community to strengthen the alliance with the staff. For example, patients busied themselves with a variety of tasks designed to lighten the burden of the staff, and for the first time in several months they thoroughly cleaned their kitchen and recreation areas. Compliance with research procedures increased, and the patients formed their own committee to monitor compliance with such tasks as the recording of self-ratings and temperatures. No objections were raised to the room changes needed to accommodate the volunteers, despite the fact that room changes had been a controversial issue in the past. Moreover, during group and individual therapy meetings, patients talked earnestly about past losses and disappointments, but with an indifference to the feelings usually associated with these experiences. This apparent alliance with the staff may have served to diminish the patients' anxiety about losing the staff's interest to the volunteers.

During this time (about 1 week before the arrival of the volunteers), the patients also seemed to be considerably more involved with one another. This increased alliance was highlighted by the apparent reconciliation of two patients who had shown intense antipathy for each other for some time. Such solidarity was relatively unusual for the patients and seemed to lack authenticity; it was as if they needed not only to lose themselves in one another's affairs but also to deny the antagonism they usually felt toward the illness in others and themselves.

Shortly after the arrival of the volunteers, the patients began to undermine overtly their carefully nurtured alliance with the staff. There was a marked increase in resistance to group and individual psychotherapy and to the prescribed routines on the unit, including research procedures. Conflict between the staff and the patients increased considerably as the staff became angered and bewildered by the change in the patients' behavior. Although there were no obvious signs that the patients' sense of shame about their illness and their patient status had increased as a result of the presence of volunteers designated "normal," it seems in retrospect that the resistance was an attempt to ward off this sense of shame.

The apparent cohesiveness among the patients also dissolved during this period. In particular, those who were healthier and on the way to recovery insisted that they were going to form their own therapy groups and activities from which the more regressed and less communicative patients would be excluded. The need for these patients to renounce any identification with the more regressed patients constituted a striking change from their earlier solicitous attitudes.

The Phase of Depressive Reaction

Although a number of patients claimed responsibility for their own psychotherapy and activities, none of the plans ever materialized. Just as alliances were first made and then broken, interest in any specific endeavor failed to be sustained. It appeared that these interests were not authentic but were diversions from feelings that had to be avoided.

At this point many patients felt frustrated and a few disparaged themselves for being unable to use their time effectively. Group and individual therapy meetings were generally unproductive, since patients continued to resist examining their feelings. Although the level of overt distress among the more recovered patients did not become particularly intense, most seemed to be in a somewhat suspended state, during which little was ventured or achieved. For the more

depressed patients the overt reaction of withdrawal was more pronounced.

A patient who had been a highly successful attorney before his illness was the first to break out of this quiescent phase by becoming acutely aware of his intense shame over an illness that he felt rendered him less functional and less human than the volunteers. In the prevailing climate of a diminished alliance with staff and an aversion to the exploration of feelings, he persevered in his request for a lengthy pass, despite what he later revealed to be a growing suicidality. Fortunately, he withdrew the request when his therapist noticed that he appeared more agitated. When confronted with these feelings during a group therapy session, he initially dealt with them by directing a great deal of anger at the staff, whom he accused of treating him as impaired. His anger seemed to catalyze other patients in the community, who emerged from their quiescence and began voicing anger at what they saw as a double standard on the unit. The volunteers had their own phone, flexible curfews, and occasional exemption from the diet; they were not subjected to lumbar puncture, their behavior was not rated, and their moods were not regularly subject to interpretation. Moreover, the patients felt that the volunteers generally received more respect from staff and administration. The patients' expression of these feelings provided a context for the elaboration of their deep sense of shame about their illness and other attributes they judged to be imperfect.

Partial Identification and Resolution of the Depressive Response

Once the patients began to become aware of previously repressed feelings, they proceeded to explore the events of the past few months. The major issue that came to light was the patients' acknowledgment that the presence of the volunteers (who by definition and in actuality were more functional than they) placed them in a situation in which they were acutely reminded of their imperfections and weaknesses. One patient stated,

> After they arrived I was faced with people who were called normal and I couldn't get away from that even though I try not to think about the fact that I've had more serious problems than most other people. For a while I began to feel that the volunteers and the staff and even the other patients saw me as a failure—like I was too weak to get through life without getting sick, and I began to feel that way about myself. . . . Somehow I got busy with all the things going on around the unit, and I didn't feel that way for long.

As these feelings emerged it became clear that our patients shared a pervasive sense of imperfection derived in part from their experience of themselves as psychiatric patients who had failed to successfully negotiate the important tasks necessary for establishing a sense of happiness and balance. Their repeated hospitalizations for affective episodes seemed to confirm this thoroughgoing sense of failure. Thus, the complex interaction of biological and psychological factors that rendered them more vulnerable to affective episodes imprinted upon them a sense of defectiveness. Moreover, this sense of defectiveness seemed to initiate a vicious cycle, in which patients viewed many of the inevitable disappointments or losses in living as further evidence of their particular inability to influence adequately the events of their lives. The extreme dysphoria associated with directly experiencing this sense of defectiveness or "negative identity" was intolerable, and elaborate defenses against it became a necessity. It is not surprising that the normal volunteers presented a particularly highly charged stimulus for the emergence of these feelings.

As the patients continued to reconstruct their experiences following the arrival of the volunteers, they recognized the defensive and avoidance function of the various energy-consuming maneuvers. They admitted that they had initially attempted to placate staff and avoid disagreement, despite the fact that this meant remaining silent over issues that hurt or angered them. They also noted their efforts to bypass staff and assume responsibility for running the unit and providing therapy for themselves. When these activities failed to produce the desired result, they turned to other avoidance defenses, particularly withdrawal from others and dampening of feelings. Although most patients were successfully defended by these avoidance maneuvers, they were also shielded from a sense of their own strengths and from the possibilities of gratification from others and therefore experienced an aching emptiness that further contributed to depression. The patient who was unable to defend against his intense shame by such maneuvers spoke movingly of the suicidality he experienced when he felt himself to be without any redeeming features. Other patients discussed similar episodes of experiencing acutely their sense of negative identity, which often (but not always) preceded suicide attempts, numbing depressions, or episodes of mania.

It was during this time that the patients began to develop friendships with the volunteers. The young man who had come so close to suicide stated,

> I began to see the volunteers as human beings who I could reach out to. Especially after we talked about how they had affected us here, I was able to pay more attention to them as people in their own right and I began to see that they had feelings like my own. As I got to like them, they seemed more interested in me as a person and this helped me to feel better. We started sharing things with one another, discussing our anxieties. Take their feelings about the research procedures—that started drawing us closer together, because we had that in common. We got to the point of joking about it. The sharing was the nicest part. A lot of the stuff like the procedures, the staff, sort of came into focus for us, nothing was held back.

As time progressed, the level of communication deepened. The volunteers began exploring the illness

with some of their patient-friends, asking, for example, "How did you get sick? It's so difficult for me to imagine that happening to you." Patients responded positively to such openness. One patient stated,

> I felt able to talk about my past and answer their questions because I could accept the problem in myself for the first time without feeling horrible about myself. Their being here helped. It was like a trial thing, having a "normal" come up to you and ask you what you know others must be wondering about all the time and then be able to answer without having to cover up. And I taught them something. I wanted to show them that even though I was hospitalized with depression I knew something about life and had something to say—and they seemed to accept my illness as a part of me, but just a part, and to see that there is more to me than that. I think they helped me to see this in myself as much as anyone else here.

Interestingly, it was not until the patients acknowledged that their experience with the volunteers had ultimately proven helpful that the staff was fully able to accept the presence of the volunteers on the unit. The staff was initially dismayed at the disruption in the milieu and saw this as a failure of the research personnel to protect the therapeutic community rather than as a manifestation of an important part of the patients' depressive process. Gradually, a number of close relationships developed between the staff and the volunteers, and many staff members came to express their gratitude to the volunteers for their warmth and openness in relating to the patients.

Although many barriers between patients and volunteers fell, some patients, particularly those with the longest history of illness, continued to feel the distinction between normal and abnormal. This sense of distinction was illustrated by an evening group meeting held shortly before one of the volunteers left the unit. The volunteer was spontaneously invited to attend as she passed the meeting room. Her description of the meeting is as follows:

> I wore a pantsuit with my robe over it and was walking by the group; perhaps it looked strange and one of them thought they had better invite me to the group before I did something drastic. When I mentioned the exact time of my leaving they said, "No, you can't go, you must stay the usual four months, because all your symptoms are right for manic-depressive illness." One said that I must also be ill and that they too had denied it, and that anyway my overdressing was characteristic.

This complex communication expressed the patients' grief and anger at the volunteer's departure, as well as residual anger at her designation as normal and apart from them. The underlying fantasy, in which the volunteer becomes a patient, in effect expresses the wish for closeness. For some patients, however, this closeness cannot exist in the realm where all acknowledge their mutual humanity but only where all are seen as patients apart from the normal community. Thus, for these patients, the volunteers were no longer the "other" but were recruited as "patients."

EFFECT ON THE NORMAL VOLUNTEERS

Although a detailed description of the reaction of the volunteers to living on our research unit is beyond the scope of this paper, a few observations can be made. Initially, the volunteers found the unit hectic and confusing. One of the volunteers had just left her boyfriend halfway across the country and felt like "crying all the time for the first few days," but she was afraid to cry because "if the staff saw me crying, they'd think I was crazy and have me in therapy before I knew it." Another volunteer described her initial discomfort around the patients:

> I had a stereotyped idea of a psychiatric ward and of patients. I felt that patients would be violent and unpredictable and would talk incomprehensibly. I actually saw one patient go into seclusion on my second day and heard certain staff members talking about having been kicked or bitten by him some months ago.

The volunteers began to question staff members about the rationale for certain interventions and limits. Initially, some thought that the staff tended to be too strict with the patients. Shortly after one volunteer voiced this opinion, a hypomanic young female patient entered the volunteer's room and insisted that she terminate a phone call to her boyfriend and speak with her. She did exactly as the patient requested. After this experience she talked with a staff member and reached the conclusion that "being direct with people about what you like and don't like is a way of showing them respect. You don't have to baby or humor anyone here, you react as you would to anyone else."

As the volunteers became more interested in the patients' behavior, they began to investigate their own feelings. For example, after a month, one volunteer noted that "the more I think about it, the more I feel that the depression the patients get is like the depression I get, only theirs seems so much more severe."

Gradually, as they grew more comfortable with the patient community, the volunteers became more open and were able to acknowledge some of their problems and occasionally asked for assistance in solving them.

Although in general the volunteers' perceptions of mentally ill people changed profoundly and they saw their common dilemmas and humanity much more deeply than before, they retained a sense that there were some important differences between the patients and themselves. In fact, the volunteers seemed to have learned about some of the crucial clinical aspects of manic-depressive illness, such as the liability to sudden affective shifts, the tendency to avoid painful emotional issues, the often unyielding perfectionism, the tendency toward self-destructiveness, and the often painfully low self-esteem. This was summed up by one of the volunteers just before she left:

I try to compare myself with patients sometimes, what makes me different. I was sad when I came here, definitely, but for some reason I could cope with it and keep my senses clear. It seemed it was easier for me to face what was bothering me than for some of the patients. Many of the patients seem to go one way or the other when they face something very painful. Maybe there is a physical factor that accounts for some of that. I think too that the patients expect too much of themselves and if they fail, it is more than they can bear. It's like their expectations are more important than they are, like they don't have a good enough feeling about themselves to begin with. Also, I have a natural instinct to stay afloat. I feel some of the patients work against themselves. For instance, if I were a lifeguard and I were involved in a rescue mission, I'd really try to save the life of the other person. But, if I recognized that I couldn't save the person, and that if I persisted I'd die, I would recognize the situation for what it was and attempt to save my own life. In other words, don't give up without a fight but don't lose yourself in a losing battle. People here lose themselves. They can't accept things, but they are not supermen, and sometimes they can't recognize they need help. I was that way a lot in my life, but it seems I could change it when I needed to.

CONCLUSIONS

The need for normative data in clinical psychobiological research set the stage for a social and psychological "experiment," in which psychiatric patients and normal volunteers were hospitalized together for several months on a psychiatric research unit. The plans we fashioned to deal with the possible problems that might arise from the experiment centered around the assumption that the volunteers would have considerably more difficulty exchanging their own familiar environment for an active psychiatric unit than the patients would have adapting to a unit that would be enlarged by a few volunteers. This assumption proved to be incorrect; we underestimated both the resiliency of the volunteers and the extent to which patients consider themselves to be inferior to those whose lives have not been disrupted by a chronic psychiatric illness.

This impoverished self-concept of our patients largely determined their complex reaction to the volunteers. The associated shame initially required a number of energy-consuming avoidance defenses. Although these diversionary maneuvers worked temporarily, it became clear that they would not solve the underlying issues, and several patients began to disparage themselves and withdrew into a numbing but insulating depression. Thus, the patients' response to the volunteers described a vicious cycle, in which their sense of failure necessitated the institution of complex defensive maneuvers, which further exacerbated their vulnerability to depression.

The patients' sense of failure, which comes in large part from their experience of themselves as chronic psychiatric patients, is particularly crucial in the predischarge period, when they face the difficult issues of separation from the hospital and reintegration into their families and communities. By admitting volunteers, we in effect brought the community to the hospital, which gave the patients an opportunity to deal with the difficulties involved in reintegration without having to deal with the complex issue of separation at the same time. Since the problems raised by reintegration occurred entirely within a therapeutic setting, they could be dealt with more reliably than in the postdischarge period. Moreover, the openness and the warmth of the volunteers facilitated the therapeutic work of the staff in leading to the considerable resolution of these highly charged issues.

The extent to which repeated psychiatric hospitalizations and recurrent affective episodes influence the self-concept of patients with affective illness underlines the importance of a program that combines psychopharmacologic and psychotherapeutic intervention in an attempt to prevent relapse of the illness. When a patient does relapse, careful attention should be paid in the predischarge period to the possibly damaging effect of his self-disparagement, since such attitudes substantially compromise the chances of a successful reintegration into his environment and enhance the likelihood of further affective episodes. The admission of normal volunteers to the unit can facilitate a more effective response to these problems.

Whatever Happened to Psychiatry? The Deprofessionalization of Community Mental Health Centers

BY PAUL J. FINK, M.D., AND STEPHEN P. WEINSTEIN, PH.D.

The authors describe the dichotomy in the concept of community mental health centers. One view regards the community mental health center as a service provider for underserved populations, and another holds that it is an agent of social change. Deprofessionalization of community mental health centers has resulted from this lack of clear purpose, curtailment of funds, and conflicts over authority, service delivery, and control of the centers. Deprofessionalization has led to a decline in the number of psychiatrists in community mental health centers and a potentially negative impact on the quality of patient care.

RECENTLY A NUMBER of papers[1] (1-5) have been published in defense of or in opposition to the community mental health center movement. A series of positive papers on mental health manpower, particularly psychiatric manpower, has noted the failure of community mental health to attract and, more importantly, to retain psychiatrists. It appears that as a result (or perhaps cause) many centers have chosen to be nonprofessional or at least to operate with few professionals on their staff. This phenomenon is extolled by some and is of great concern to others. Another disturbing phenomenon is the lack of understanding of the concept of community mental health and the mission of community mental health centers. There is no uniformity in the understanding of the concept, and there is sufficient misunderstanding to result in a great deal of confusion, not only among those working in community mental health centers but also among the observers, funding agencies, legislators, academicians, and, of course, the consumers.

This article addresses the issues surrounding the ambiguity of the community mental health concept and the roles of professionals and nonprofessionals within a community mental health framework.

TWO VIEWS OF CMHCS

There are several dichotomies that express the problems and areas of conflict in the community mental health movement. Is it merely a new type of delivery system or an entirely new concept? Is mental health a euphemism for mental illness or is it an attempt to satisfy community needs, resulting in happiness for all citizens? Are community mental health centers social welfare agencies or health (medical model) agencies? Were community mental health centers created to care for the seriously mentally ill or to solve the community's problems? Can all persons designated as therapists deliver the same quality of care regardless of education, training, background, or experience or are such credentials necessary in service delivery roles?

In response to the Community Mental Health Centers Act of 1963 and its amendments, two distinct schools of thought developed. One group believed the act was designed to 1) provide access to psychiatric care for the millions of citizens who could not afford private care; 2) provide care for the seriously mentally ill closer to home in their own communities thus obviating the need to send them off to a remote state hospital; and 3) develop organized care settings throughout the nation, thereby developing a team approach in the delivery of care to mentally ill and emotionally disturbed persons.

Another group apparently saw the community mental health center as an entirely different type of agency, one that would address the problems of mental illness by ridding the community of what were presumed to be the causes of mental illness: poverty racism, unemployment, poor housing, crime, riots, etc.

Langsley, an early leader in the community mental health movement, recently expressed his views regarding this dichotomy:

> The attempt to meet all needs of all people—the attempt to make community mental health programs responsible for the quality of life rather than for the treatment and pre-

Received March 1, 1978; revised July 14, 1978; accepted Sept. 26, 1978.

> vention of illness, is a distortion of the original program, its legislation and its intent, at least in my opinion. (personal communication, January 1978)

The concern for the community's social needs versus the needs of mental patients, of prevention versus treatment, of social services versus psychiatric services, has become the universal area of conflict surrounding the community mental health movement. Public Law 94-63 and other public documents support the concept of community control of community mental health centers, thereby moving community boards away from advisory roles toward governing roles. This is destined to reshape the definition of community mental health as a narrow focus of treatment into a broader concept defined by the community. This situation is most effectively explicated by Zwerling (6) in a variety of definitions that are the result of a special effort to redefine community mental health and to distinguish it from traditional mental health practice. According to Zwerling the fundamental components of community mental health are that

> first, the target of effort is the entire population of a defined community, rather than persons identified as "patients"; second, it seeks to achieve the maintenance and promotion of health rather than to devote exclusive concern to the treatment of illness; third, it seeks an understanding of the family, community, social class and cultural sources of human disturbance in addition to its biological and psychological sources and in turn the promotion of mental health by intervention in family, community, social class and cultural structures rather than only in biological and psychic structures. (6, p. 25)

The legislation establishing community mental health centers mandated five basic services: inpatient, outpatient, emergency, partial hospitalization, and consultation-education. The first four were designed to provide direct treatment to sick people. Consultation-education was viewed by many as a highly experimental "service"; it was frequently interpreted as the preventive area of the center and it became a focus of community groups and social changers. In understanding community mental health as a force for social change many communities maintained a plea for increases in this "preventive service." However, as Langsley pointed out there is no hard evidence for the ability of the field to prevent mental illness and the scientific base for such prevention is at best rudimentary. The demands for preventive services are often more a matter of rhetoric than substance, but, more importantly, these demands reflect a basic misunderstanding or misreading of the purpose of the community mental health effort. In fact, many consultation and education services do address themselves to aspects of preventive psychiatry in the context of a more narrowly defined mission than that described by those who see community mental health centers as social change agents rather than service delivery agencies.

If the fulfillment of the social change definitions were possible, it would take far more funds than have been allocated to the entire community mental health center movement. The available funds can barely pay for direct services, and if the current center funding is not specifically for direct patient care services then there is no existing federal structure to fund such services and what began as an academic difference of opinion around definitions escalates into a crisis in the treatment of mental illness. The direction taken by NIMH in its Forward Plan (7) was to move toward having all psychiatric services in the nation performed in community mental health centers. However, the confusion between the role of the mental health center and the delivery of mental health services places psychiatry in a tenuous if not treacherous position, particularly if the nontreatment or social change definition of mental health persists.

REDUCED PROFESSIONAL INVOLVEMENT

In addition to this disconcerting situation, a concurrent trend has been evolving within the community mental health center system—deprofessionalization. This involves a gradual movement away from the use of professionals in both the administration of centers and direct treatment of patients. This emerging climate appears to be a repetition of the situation that developed in the state hospital system earlier in this century, when the quality of patient care deteriorated, professional involvement was reduced or eliminated, and the hospitals became repositories for the poor. Issues of turf, funds, and the objectives of the community mental health center movement provide the causal framework for the current efforts at deprofessionalization, particularly in respect to psychiatry.

Between 1970 and 1975 the number of full-time-equivalent psychiatrists in community mental health centers dropped from 6.8 to 4.3 per center (8, p. 25, table 2; 9) even though the total staff of these centers almost tripled during the same period. The number of psychologists nearly doubled (from 4.9 to 8.5) and social workers increased from 9.7 to 12.2 full-time equivalents per center during that time. Staffs have been supplemented by paraprofessionals and indigenous workers.

Threats to Psychiatrists' Involvement

From the beginning of the community mental health center movement there was an effort to use community residents (indigenous workers) to deliver some services because of their familiarity with their own ethnic group in the community. This role became distorted to the point where such workers felt and were supported in the belief that their therapeutic interventions were at least equivalent to those delivered by trained professionals. Appropriate life experience and a six-week inservice training program somehow was

interpreted as the equivalent of a medical school education and three years of residency. Once one denies that a psychiatrist, psychologist, social worker, or psychiatric nurse has any unique training, skill, or theoretical framework, the leap to an antiprofessional point of view is simple. In fact, if the goal of community mental health is to make the community a better place to live, then professionals may have little to offer in their capacities as therapists.

Even within the more traditional concept of the community mental health center, continuing conflicts among the various professionals for authority and control have weakened the position of all professionals. This has resulted in undue pressure on the system to eliminate, where possible, psychiatrists from all controlling positions despite their skills at organizing and developing clinical services and despite their training (or, for that matter, lack of training) in administration.

Being the highest paid professional within a community mental health center has been a triple-edged sword. First, psychiatrists' services are expensive, thereby restricting the number hired. In their place large numbers of personnel with less or different training whose concept of community mental health and approaches to patients were very different were hired. Second, psychiatrists assumed that centers were medical agencies and that doctors therefore were the highest authorities. Finally, psychiatrists frequently were needed only to prescribe medications where large numbers of chronically mentally ill patients were treated, thereby limiting their program involvement. In a setting in which community mental health was seen as an agent of social change, psychiatrists maintained a psychodynamic orientation and a general belief that patients in some way contributed to their own distress, so that they were driven out of the center, embroiled in a continual battle with other members of the staff and community, or co-opted, agreeing that they had very little different to offer. In general, community mental health centers became relatively unsatisfactory places for psychiatrists to work.

The situation is further exacerbated by available funding mechanisms, which make it less advantageous for centers to adhere to the medical model and retain a significant number of psychiatrists on the staff. As a center's federal funds are reduced, the administration must turn to state and local resources to support the level of effort they had developed. However, these sources lack the broad federal tax base (i.e., funds) and are forced to tell centers to reduce staff or services. When this is combined with an antiprofessional community bias, the most straightforward conclusion is to save money by eliminating the higher priced personnel and substituting more cheaply acquired mental health workers. This view is frequently tacitly supported, if not fully endorsed, by government officials who for the most part are not themselves psychiatrists and frequently hold the view that professionals are not necessary for the delivery of mental health services.

The Fallacy of the Social Change Definition

The guarantee of good health for all is a marvelous concept but should be understood to be a practical impossibility. The best we can hope to guarantee is the availability of health *care*. This distortion is by no means minor and in fact tends to support the trend toward deprofessionalization. It is easy to see why some say that the medical model of service delivery should be supplanted or replaced by a social action model or for some to call for a redefining of mental illness because of an increasing belief among both professionals and the public that many individuals considered mentally ill by mental health professionals are in fact persons who are appropriately responding to stresses in their environment. If health is guaranteed and manipulation of the environment can provide health, then psychiatrists and psychologists, who are trained to understand and help people change their behavior, have no legitimate place in such a system.

Despite being a part of the rhetoric, the issue of quality of care is rarely studied or addressed directly. It becomes clear from this vicious circle that the quality of care will deteriorate, the individual patient will lose, and the nature of centers will change. What was hailed as an opportunity for all citizens to have equal access to quality care is degenerating into another two-class system in which the poor will once again receive inferior care from less qualified workers who have been seen through rationalization to provide equal quality services.

Deprofessionalization can be seen as resulting from a confluence of mistaken ideas, not the least of which is the strange confusion between illness and health and the even stranger confusion between health and health care. Zwerling cites "the recognition of health, including mental health, as a right of all, and not as a privilege available for purchase by those who can afford the services" (6, p. 81) as one of the essential components of community mental health.

As prestigious a figure in American medicine as John Knowles in a recent article directed our attention to the same seemingly innocent error. It is not clear if he himself believes it or if he is pointing out the unreality of it:

> The evolution of the various professional, governmental and consumer groups interested in, and responsible for, health—now viewed by most American citizens as a fundamental "right"—represents a typical American response. (10, p. 5)

CONCLUSIONS

For a number of years psychiatrists have attempted to define their role (11–13). Specifically, these definitional efforts have tended to place great emphasis on the care of the seriously mentally ill and the biological aspects of mental illness. Where the role of psychiatrists and other professionals has become equivocal

has been in those areas where others have professed equal facility in the treatment of specific conditions and in a system that emphasizes social change over patient care.

Whatever happened to psychiatry? is not an idle question. If all psychiatric funding is relabeled mental health funding and if psychiatry is then found to be irrelevant to community mental health, which is viewed as an agent of social change, then psychiatrists can look forward to a severely diminished role in the entire mental health/mental illness system. At the risk of professing professionalism and elitism, we suggest that the delivery of services to people with problems, whether marital and family problems or schizophrenia, should be monitored if not delivered by professionals. To achieve this objective it is imperative that clarity be brought to the definition, goals, and purposes of community mental health centers and that in lieu of an idealistic, clearly unachievable goal of bringing "mental health" and the "good life" to every community in America we narrow our focus to an achievable goal of providing access to and care for millions of mentally ill and emotionally disturbed citizens. In such a system, professionals would be responsible for the services delivered and would receive the regard consistent with that role. Similarly, community workers, paraprofessionals, and citizen volunteers would have appropriate positions, roles, and tasks within a system organized according to the medical model. It is possible to develop a system of services that is both needed and desired by the community and that affords patients dignity in addition to excellent care. There is no disagreement with Zwerling's statement that

> the thing that we're about is dignity. It's important that a person sees himself as having some worth, and I contend that a service should be developed in a way that a person can work better and serve in dignity, as well as have service in dignity. (6, p. 123)

If it is no longer possible to make the community mental health center system an outstanding therapeutic service delivery system we must immediately redefine it so that it will be clearly distinguishable from psychiatric treatment and rehabilitation and each system can proceed to greater definition, autonomy, growth, and achievement.

Plasma Growth Hormone: Effect of Anxiety During Flooding in Vivo

BY GEORGE C. CURTIS, M.D., RANDOLPH NESSE, M.D., MARTIN BUXTON, M.D., AND DAVID LIPPMAN, M.D.

The treatment of phobias by rapid in vivo exposure to the feared situation was accompanied by an increase in plasma growth hormone levels on at least one of two occasions in 8 of 11 subjects. The average growth hormone response was greater on the second occasion, even though subjective anxiety was less. Plasma growth hormone was not elevated during the subjects' adaptation to the laboratory. Strong subjective and behavioral anxiety responses failed to elevate plasma growth hormone levels in some subjects. The probability of a growth hormone response was the same whether or not baseline levels were elevated prior to exposure.

PLASMA GROWTH hormone levels are elevated in man and animals by a variety of physiological and psychological stimuli (1). Little is known about the specific psychological events triggering growth hormone release in man. There have been several reports of growth hormone elevations in situations that are presumably emotionally arousing, such as venipuncture (2, 3), cardiac catheterization (4), gastroscopy (5), arousing movies (6), final examinations (7), and stress interviews (8). However, apparently only a minority of subjects studied in these situations prove to be growth hormone responders. With the possible exception of Greene and associates' study of patients undergoing cardiac catheterization (4), most of the work involving humans has been conducted in situations that are only mildly arousing. Affective arousal independently assessed by psychological methods has been reported by some researchers (8) to distinguish growth hormone responders from nonresponders; other researchers (3, 6) have reported that it does not. One report (5) suggested that anticipation of an arousing experience may have a greater effect on growth hormone than does the event itself, a finding reminiscent of much work in the corticosteroid field (9).

The treatment of severe specific phobias by flooding in vivo produces anxiety responses that are usually quite powerful as judged by behavioral and subjective criteria (10), and to some extent by autonomic (11) and corticosteroid responsiveness (12, 13). We now report the results of 2 experiments using this approach for a further assessment of the relationship between anxiety and growth hormone secretion.

METHOD

The subjects consisted of 11 medically healthy, medication-free persons (9 women aged 20–52 and 2 men aged 25 and 42) with severe phobias for physical objects (e.g., snakes, spiders, birds) manifested by panic on encountering the phobic stimulus and by a fixed pattern of elaborate, irrational, life-restricting maneuvers to avoid encountering it, often including avoidance of photographs or motion pictures of the object. One 52-year-old woman had stopped menstruating 2 years previously but denied hot flashes or other menopausal symptoms. The remaining women, all in their 20s and early 30s, were menstruating normally.

The design of the study was disclosed to each subject in advance, and informed consent was obtained. Each subject spent 5 three-hour sessions in the laboratory on separate days. At 20-minute intervals throughout each session, blood samples were taken through an indwelling needle, and the Subjective Units of Distress were self-rated on an analogue scale of 0 (no distress) to 100 (maximal distress).

With exceptions to be noted, the subjects sat quietly throughout every session, engaging in self-selected sedentary activities, such as reading or working crossword puzzles. The first 2 sessions were for adaptation. During the second hour of the third and fourth sessions, the phobia was treated by flooding in vivo. This consisted of live confrontation with the phobic stimulus at the maximum rate that the subject would allow, keeping anxiety at the maximum tolerable level until it

Presented in part at a New Research session at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received March 8, 1978; revised May 30, 1978; accepted July 18, 1978.

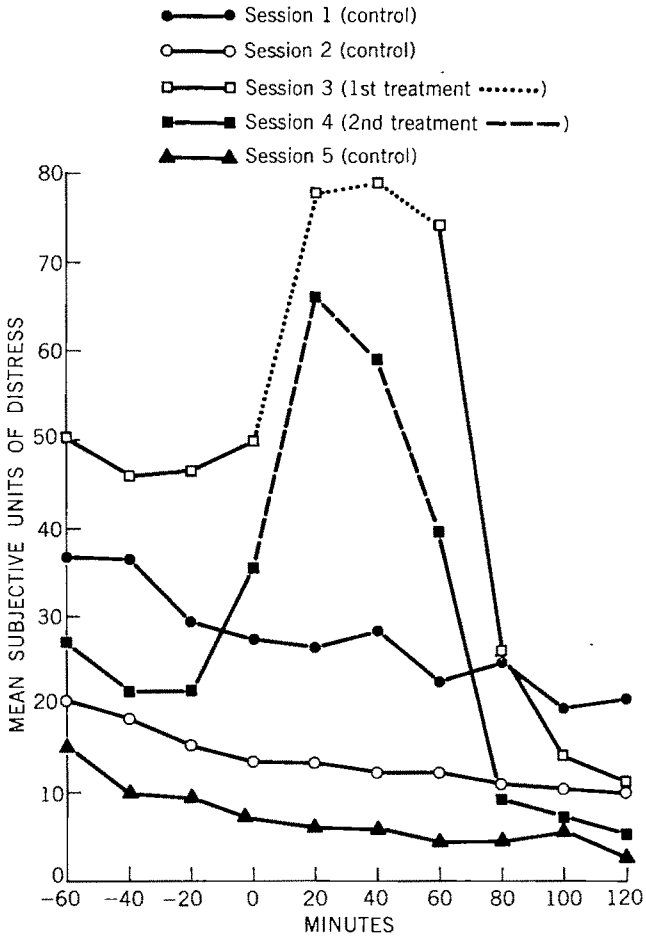
subsided and the patient became comfortable in the presence of the stimulus. The fifth session was a control. During the middle hour of the adaptation and control sessions, the subjects were engaged in casual conversation in order to control for the presence of another person during the hours corresponding to the flooding therapy. If additional treatment was needed and desired, it was given at a later date without further blood sampling.

In order to determine the beginning time of the laboratory sessions, each subject recorded his or her time of rising and retiring for 14 days. From these records each subject's average time of midsleep was computed and used as the zero reference for his or her circadian phase. In one experiment with 6 of the subjects, sessions in the laboratory began 3 hours after the individual's average time of midsleep, usually around 7:00 a.m. In the other experiment with 5 subjects, sessions began 15 hours after the individual's average time of midsleep, usually around 7:00 p.m.

Growth hormone was measured by radioimmunoassay (14). Plasma cortisol findings in these subjects have been reported elsewhere (12, 13).

RESULTS



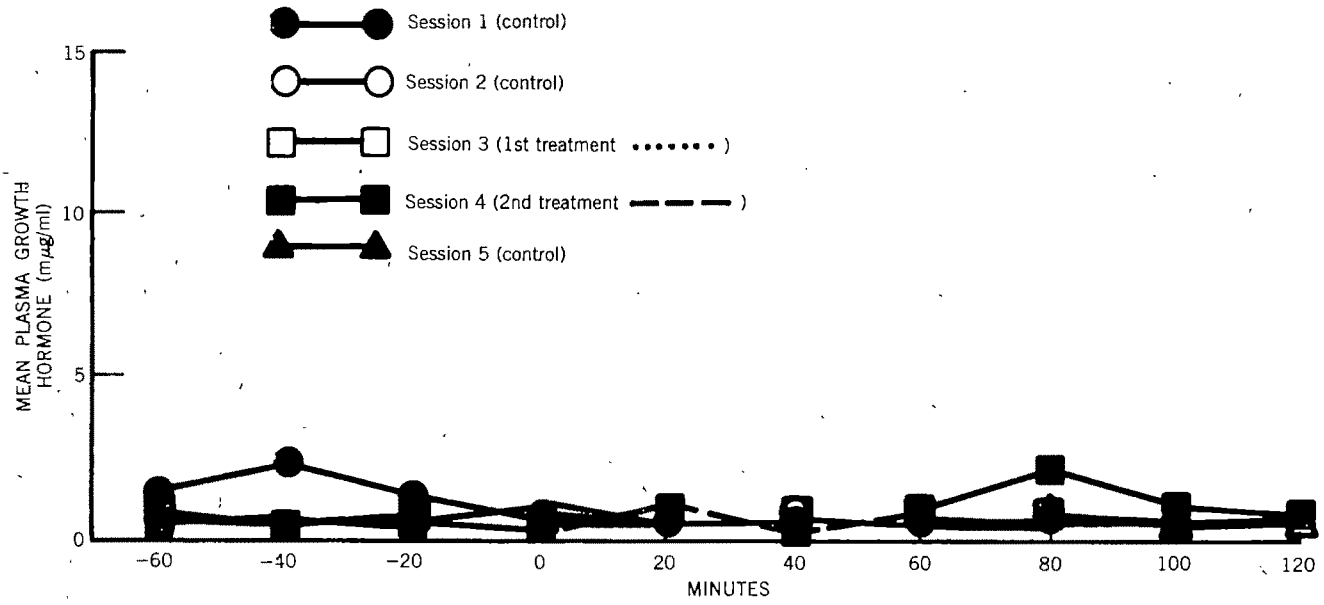
Although not entirely uniform across subjects or across time, the affective response to flooding in vivo was regularly intense, often including weeping, screaming, attempts to get away, gross tremors, chattering teeth, gooseflesh, and rapid, labile heartbeat. As these manifestations subsided at one level of exposure, the therapist pushed rapidly ahead to more intense exposure. Overall, it was a grueling experience, usually described as the most frightening of the patient's life.

Data analyses of growth hormone levels and self-ratings of anxiety from the two experiments yielded similar results and conclusions. Therefore the two data sets were pooled and will be reported as a single experiment.

Figure 1 presents ratings of Subjective Units of Distress averaged across all 11 subjects at each time point within each session. The levels were usually low, except for moderate elevations during the initial adaptation session and prior to the treatment hours and for marked elevations during the two treatment hours in sessions 3 and 4. Subjects usually attributed their uneasiness during session 1 to the experiment as a whole or to blood drawing. A few mentioned fear of the possibility of being confronted with the phobic stimulus immediately, although they had been assured that this would not happen until session 3. During the anticipatory uneasiness in session 1 the subjects did not appear intensely disturbed, as they did before and during the confrontation itself. Uneasiness prior to treatment hours was regularly attributed to anticipation of treatment.

Three-way analyses of variance (Sessions×Subjects×Time-Within-Sessions) of the data on Subjective Units of Distress yielded Sessions×Time-Within-Sessions interactions significant at the .001 level, reflecting mainly the large rise during flooding. Subject×Session interactions were also significant ($p<.001$), reflecting mainly individual differences in self-reported distress at times other than flooding. Main effects of Subjects, Sessions, and Time-Within-Sessions were also significant at levels ranging from .05 to .001.

FIGURE 1
Mean Subjective Distress Ratings for All 11 Subjects[a]



[a]Flooding from 0–60 minutes in sessions 3 and 4.

Growth hormone levels were quite labile in some subjects and stable in others. Some of the lability coincided with flooding, but a great deal did not. Some subjects appeared to make strong growth hormone responses to flooding while others clearly made no response at all.

When growth hormone data for each time point were averaged across subjects, suggestive rises during flooding occurred in both groups of subjects, but they were not confirmed by significant main effects of Sessions or by Sessions×Time-Within-Sessions interactions in either group. The main effects of Subjects and the Subjects×Sessions interactions were significant ($p<.005$ or better).

FIGURE 2
Mean Plasma Growth Hormone Values in a 25-Year-Old Male Nonresponder[a]

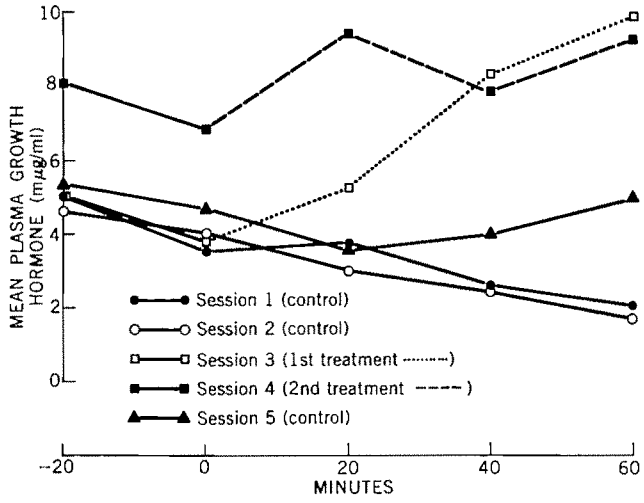
[a]Flooding from 0–60 minutes in sessions 3 and 4.

A separate analysis of the data from each subject in order to examine the interactions revealed significant main effects of Sessions in 5 of the 11 subjects. In every case the highest mean growth hormone level occurred during one of the sessions containing a treatment hour. Contrary to the cortisol results (12, 13), there was not even a suggestive tendency toward growth hormone elevation in session 1. Averaging the values across sessions diluted any effect of flooding, since each treatment hour was preceded and followed by a nontreatment hour.

Three of the 11 subjects showed significant main effects of Time-Within-Sessions. In one, this was due to elevations during the first hour in most sessions, in one to elevations during the third hour of most sessions, and in one to elevations during the first and third hours.

Thus, 4 main types of individual response patterns were noted: 1) near-zero values at all times, as in figure 2; 2) many elevations, mainly in the first and/or third hours of most sessions, and apparently unrelated to flooding; 3) a relatively specific response to flooding, greater during the first treatment hour (session 3); and 4) a relatively specific response to flooding, greater during the second treatment hour (session 4). Pattern 4 was observed most frequently. The foregoing results suggest a specific effect of flooding, perhaps obscured by individual differences and by unexplained baseline lability, primarily during the hours preceding and following those which corresponded with flooding. Consequently, a three-way analysis of variance was performed using data from all subjects and all sessions, but using only the 2 time points immediately before and the 3 time points during the flooding hours, together with matching time points from adaptation and control sessions (−20 minutes through +60 minutes in figures 1 and 2).

The results of this analysis are summarized in table 1. They are similar to the results from analysis of all data points from the two experiments separately, except that the main effect of Sessions is now significant at the .01 level. Figure 3 depicts the values, averaged across subjects for each time point within each session. This illustration shows mean elevations attributable to flooding and suggests a possible enhancement of response at the second treatment, with perhaps an anticipatory rise before the second, but not the first, treatment. However, the interactions still point to great individual differences in terms of responders and nonresponders.



Considerable evidence (15–17) suggests that growth hormone responses to stimuli may be inhibited if baseline values are elevated just prior to the stimulus. Since values were labile in some of the present subjects, could elevated baseline values account for some of the nonresponses to flooding? This does not seem to be the case.

If baseline elevation is defined as 5 mμg/ml or more, and response as a rise of 5 mμg/ml or more above baseline, 8 of the 11 subjects responded in one of the treatment hours and of these, 7 subjects responded in both. If the baseline was not elevated, responses occurred in 64% of the treatment hours and in 12% of the matching control hours. If the baseline was elevated, the corresponding percentages were 63% and 0%. The mixed between-and-within-subject design precludes performing most nonparametric statistical analyses of this finding.

DISCUSSION

Many factors have been proposed to explain the extreme lability of plasma growth hormone levels (18), but even in studies in which such factors as falling blood glucose levels (19, 20), exercise (21, 22), and venipuncture (23) have been controlled, there are still frequent unexplainable episodes of growth hormone secretion (21). These must be taken into account in psychophysiological studies. Women are usually found to show greater lability than men (19). This may account for the somewhat greater baseline lability in the present study than in several others in which men comprised a higher proportion of the subjects (3, 4, 6, 8).

Other factors are difficult to evaluate. Brown and Heninger's subjects (3, 6) were studied after an 8-hour fast, whereas those of Greene and associates (4) were given a light breakfast, a glucose infusion, 75 mg of sodium pentobarbital, and 25 mg of promethazine. Our patients were drug free, but there were no dietary restrictions; no such restrictions were described by Abplanalp and associates (8) or by Kurokawa and associates (5), although some of the subjects of the latter study underwent gastroscopy and were presumably fasting. Venipuncture or intravenous catheterization is reported to provoke growth hormone release in one-third or fewer of subjects and to do so on repetition in most of those who respond the first time (2, 3). This could account for the consistent and statistically significant elevations early in most sessions in 2 of our female subjects. Replacement of a nonfunctioning needle or catheter was too infrequent to evaluate its effect, although we occasionally observed both rises and nonrises following this type of event. Rises during the third hour in most sessions by 2 subjects may have been due to a postprandial fall in blood glucose (24).

The percentage of subjects with growth hormone responses to the psychological stimulus was somewhat higher in the present study—55% on both occasions, 73% on one occasion or the other—than the approximately 33% reported by others (2–4, 6, 8). This may be because the anxiety stimulus used in the present study was quite potent. Present findings support previous ones (3), in that responders on one occasion tended to remain responders on the next, and nonresponders tended to remain nonresponders. An elevated baseline level does not appear to affect the growth hormone response to flooding, since the probability of a response was the same (63%–64%) whether or not the baseline was elevated. Growth hormone responses were certainly not diminished, and may have been enhanced, on the second exposure to the same anxiety stimulus, even though the subjective and behavioral responses were diminished. If confirmed, this would define a difference from the behavior of cortisol, which tends to respond early, even before the encounter with the phobic stimulus, and to damp out rapidly (12, 13). This could be a further example of what behavior therapists call desynchrony of fear (25, 26). One interesting although tentative interpretation of this is that growth hormone responses may have been classically conditioned while cortisol and subjective responses were being extinguished. In further contrast to the case with cortisol (12, 13), these results give no reason to suspect differential responsiveness at different circadian phases.

Even intense anxiety may fail to stimulate any detectable growth hormone secretion. In the past it has often been tempting to use such a finding to challenge the reality of the anxiety. In the present instance, we can find no basis for such an inference.

Although there were only 2 men in the present study, both had low baselines with little variability, and both were nonresponders on both occasions of flooding. This is consistent with the frequent finding that women are more responsive than men. Three of the 9 women also failed to respond to one or both flooding hours, but of these, 2 had numerous peaks at other times. The responses of the 1 postmenopausal woman were not particularly remarkable; her values were somewhat less labile than those of some of the

younger women, but she did show a baseline elevation and a response to the first flooding session.

As explanations of growth hormone response and nonresponse, variations in manifest affect or in baseline growth hormone values become less attractive, thus enhancing the relative appeal of psychological factors other than affect. For example, nonresponders have been reported to score higher than responders on measures of social engagement (4, 5), field dependence (3), and Type A behavior (27) and lower on the Nowlis factor for egotism (3). These variables seem to warrant further investigation.

court. However, our own experience as well as that of other investigators (17) suggests that although personal histories can be valuable clinically, they are notoriously unreliable regarding numbers of illnesses and dates of medical events, information essential to this study.

Data from other public and private medical facilities were unavailable because of issues of confidentiality; however, as far as we could determine, our two populations had equal access to other community resources, which makes it unlikely that one group made greater use of such clinics than the other. Furthermore, serious accidents and illnesses would have most likely been referred to the hospital. The choice of private medical care was relatively rare in both groups because of financial considerations. At the time of the study, the hospital selected tended to be used by the less affluent in the community as a source of primary care. Finally, case loss would create underestimates of the actual prevalence of disorders and use of medical facilities in both groups.

We assessed medical records in terms of numbers of visits to the hospital, timing of visits, use made of different hospital services (e.g., emergency room, clinics, and wards), and reasons for visits (e.g., accidents, head or face trauma, respiratory illnesses, child abuse, and psychiatric problems).

RESULTS

The numbers of hospital visits were similar in the two groups. Incarcerated delinquents averaged 15.818 visits, compared with 13.131 visits for nonincarcerated delinquents. There was a slight tendency for incarcerated delinquents to have made more emergency room visits than nonincarcerated delinquents; incarcerated children averaged 8.974 emergency room visits, compared with 5.714 emergency room visits for nonincarcerated delinquents ($t=1.949$, $p=.054$). The numbers of clinic visits and ward admissions were almost identical in the two groups.

The greatest differences between the medical histories of the two groups emerged from an analysis of the reasons for hospital visits and from a study of the symptomatology noted in hospital charts. Although similar percentages of children in each group had been treated at one time or another for accidents or injuries (72.7% of incarcerated delinquents versus 71.1% of nonincarcerated delinquents), incarcerated children were significantly more likely to have sustained a head or face injury (62.3% versus 44.6%, $\chi^2=4.371$, $p=.037$, Yates's correction applied). A measure of the severity of head injuries sustained by the two groups was reflected in the difference between the proportion of children who received skull X rays. In the incarcerated group, 33.8% of the children had received a skull X ray, compared with 13.1% of the nonincarcerated group ($\chi^2=8.566$, $p=.004$, Yates's correction applied). Numbers of visits for head and face injuries were also significantly greater in the incarcerated group (1.026 for incarcerated versus .607 for nonincarcerated children, $t=2.072$, $p=.04$). Of special note was the finding of a significant difference in numbers of head injuries before age 2 (.091 versus .012, $t=2.329$, $p=.022$).

Also, child abuse was noted more frequently in the medical charts of incarcerated children (10.4%) than in the charts of nonincarcerated children (3.6%). It was our impression from previous clinical and epidemiological studies that abuse was underrecognized in both groups.

Of particular note was the finding that perinatal difficulties were significantly more prevalent in the histories of incarcerated delinquents than in the records of nonincarcerated delinquents. Information about pregnancy, delivery, and the immediate postnatal period was available in the charts of 41 incarcerated delinquents and 50 nonincarcerated delinquents. Of the incarcerated delinquents for whom any information was available, 36.6% had histories of perinatal difficulties, compared with 8.0% of nonincarcerated delinquents on whom information existed ($\chi^2=9.480$, $p=.003$, Yates's correction applied). These perinatal difficulties ranged from maternal syphilis to postnatal apnea requiring intubation.

Psychiatric symptoms were found more commonly in the medical records of incarcerated delinquents (44.2% versus 26.2% of nonincarcerated children) ($\chi^2=4.951$, $p=.027$, Yates's correction applied).

In an effort to determine which combination of medical history variables investigated in this study best distinguished the incarcerated delinquent group from the nonincarcerated delinquent group, a multiple regression analysis was conducted, using membership in the incarcerated or nonincarcerated group as the dependent variable. Predictor variables were presence of perinatal difficulties, child abuse, psychiatric symptoms in the subjects, number of emergency room visits, clinic visits, ward admissions, accidents or injuries, head or face injuries, and visits for upper respiratory infections before age 16. (It should be noted that the results of a multiple regression analysis in this two-group situation are identical to those of a discriminant function analysis in a greater than two-group situation [18].) Two variables, presence of perinatal difficulties and number of head and face injuries, produced an R of .382, accounting for 14.6% of the total variance. Presence of perinatal difficulties accounted for 12% of the total variance and number of head and face injuries for another 2.6%.

We were also interested in determining whether there was a combination of variables that was especially effective in distinguishing the two groups relatively early in their lives. Consequently, another multiple regression analysis was conducted, using membership in the incarcerated or nonincarcerated group as the dependent variable and, as independent variables, presence of perinatal difficulties, number of emergency room visits, number of clinic visits, num-

ber of ward admissions, number of accidents and injuries, number of head and face injuries, and number of visits for upper respiratory infections, all before age four. The results of this analysis were remarkably similar to those reported above. The combination of presence of perinatal difficulties and number of head or face injuries before age four produced an R of .365, accounting for 13.3% of the total variance. Presence of perinatal difficulties accounted for 12% of the total variance and number of head and face injuries before age four for an additional 1.3%.

To summarize, perinatal difficulties and head and face injuries most clearly distinguished incarcerated from nonincarcerated delinquents, a pattern of findings evident from early childhood through adolescence. There were also tendencies for abuse to be more prevalent in the histories of incarcerated delinquents and for psychiatric symptoms to be noted more often in histories of incarcerated children. On the basis of our clinical observations we were surprised that the presence of child abuse failed to distinguish the two groups at conventional levels of statistical significance. When we reexamined the medical records, we became convinced that the presence of child abuse was significantly underrecognized in the histories of the incarcerated group. It is our clinical impression that the incarcerated children constituted an especially abused group.

ESPECIALLY VIOLENT DELINQUENTS

We wondered whether differences in medical histories existed between more and less violent children within the incarcerated delinquent population.

At the time of this study, a new "secure unit" for especially dangerous juveniles from all over Connecticut had been constructed at the correctional school where our study sample was incarcerated. Over a 9-month period, 11 children from the New Haven area with histories of particularly violent offenses had been placed on this secure unit. We decided to compare the medical histories of this especially aggressive group with the medical histories of the general correctional school population. Because of the small number of secure-unit children from the New Haven area, we did not attempt to match for age or race in our comparison sample. We decided instead to match only for sex and geographic area. That is, since all 11 secure-unit children were male, we compared them with a random sample of 56 male delinquents from the New Haven area who had been incarcerated at the school but had not been placed in secure custody. All of the 11 secure-unit children had committed serious offenses against persons (e.g., assault, rape, arson), compared with 51% of the regularly incarcerated boys.

A comparison of secure-unit boys and the regularly incarcerated boys indicated that the secure-unit population was significantly younger than the comparison group at the time of hospital record review (179 months versus 263 months, $t=5.654$, $p<.001$). Of the secure-unit boys, 40.0% were white, compared with 62.5% of the incarcerated group. This difference was not significant.

Although total numbers of hospital visits did not differ significantly between the groups, ward admissions, especially those before age 2, tended to be greater in number for secure-unit children (1.000 versus 0.577, 0.182 versus 0.038 before age 2). Secure-unit boys tended to have more accidents and injuries before age 14; they also tended to have abuse or neglect and head and face injuries noted in their hospital charts more often than regularly incarcerated boys, but the differences did not reach conventional levels of significance.

Of the 6 secure-unit boys for whom perinatal data were available, 5 (83.3%) had perinatal difficulties, compared with 9 of 32 regularly incarcerated boys (28.1%) for whom perinatal data were available ($p=.019$, Fisher's exact test). Thus, significantly more violent offenders had perinatal problems. Moreover, our sample of violent offenders tended to have more accidents and injuries, ward admissions, and abuse than their less violent incarcerated peers.

DISCUSSION

On the basis of our clinical and epidemiological findings, it would seem that serious delinquents had extremely serious medical histories. Head and face traumas were numerous and severe in serious delinquents.

We must modify our previous report that delinquent children were no more likely to suffer from perinatal trauma than nondelinquent children. Our previous study focused on children with minor delinquencies. Seriously delinquent children, particularly those who had committed violent acts, were significantly more likely to have sustained perinatal trauma than the average delinquent child. Furthermore, seriously delinquent incarcerated children were likely to have been physically abused and/or neglected, although such abuse was underrecognized by hospital personnel.

On the basis of our present study of medical histories and our past work on the relationship of delinquency and psychopathology, there would seem to be identifiable biopsychosocial factors that together contribute to violent delinquent behavior. The combination of trauma to the central nervous system, parental psychopathology (14) (often expressed through incredible physical and psychological abuse), and social deprivation (particularly as manifested by the failure of physicians to recognize and appropriately treat psychiatric illness and/or central nervous system dysfunction in lower socioeconomic group children) creates the kind of serious, often violent, delinquent acts so prevalent in our society today.

We found that trauma to the central nervous system occurred early, either in the form of perinatal diffi-

culties or accidents and injuries. This finding has possible implications for primary prevention of some serious delinquency.

We would suggest that a single factor (e.g., brain damage, social deprivation, vulnerability to psychosis) is insufficient to engender violent delinquency. Unfortunately, often the combination of familial vulnerability (e.g., as indexed by the presence of a schizophrenic parent), trauma to the central nervous system (e.g., perinatal trauma, head injury), physical and psychological abuse from a parent, and social deprivation (e.g., failure of a physician to diagnose and treat correctly, or failure of society to provide adequate support systems in the form of community programs or residential treatment) is sufficient to create the violent young offender, and this combination of factors occurs frequently.

The Relationship of Early Maternal Separation to Borderline Personality in Children and Adolescents: A Pilot Study

BY SUSAN J. BRADLEY, M.D.

The author compared 14 child and adolescent borderline patients, diagnosed by the criteria of Gunderson and Singer (1), with a control population for history of separation from the mother or significant caretaker before age 10. The borderline patients experienced a statistically greater number of separations than the psychotic controls, the nonpsychotic psychiatric controls, and the non-psychiatrically-referred delinquent controls before age 5 but not between ages 5 and 10. The author concludes that the study provides statistical support for the theoretic role of disruption of the early infant-mother bond in borderline pathology.

THE GROUP OF individuals labeled "borderline" is a somewhat controversial population, about whom much has been written (see reference 1). However, until the paper by Gunderson and Singer (1) appeared, the literature lacked a base from which research into etiologic factors could proceed. These authors identified six criteria, generally accepted by other writers as well, to characterize borderline persons. They are 1) the presence of intense affect, usually depressive or hostile; 2) a history of impulsive behavior; 3) social adaptiveness; 4) brief psychotic experiences; 5) bizarre, dereistic, illogical, or primitive responses on unstructured psychological tests such as the Rorschach but not on more structured tests such as the Wechsler Adult Intelligence Scale; and 6) relationships that vacillate between transient superficiality and intense dependency.

Etiologic theories of the borderline personality (2, 3) have not been validated, partly because of the lack of acceptable diagnostic criteria but also because of the difficulty in defining and measuring some of the hypothesized variables. Although still partially theoretic, works such as those of Bowlby (4–6) on the process of attachment and the effects of separation in children and of Mahler and associates (7) on the separation-individuation process and its vicissitudes provide insight into variables of likely relevance, some of which are measurable.

Bowlby (4) has stressed the generally deleterious effect of early parent-child separation and supports his position with studies that demonstrate an increased incidence of early parental loss in psychiatric patients, depressed persons, and juvenile delinquents. Some studies (8, 9) have reported that the incidence of early parental loss in sociopaths is particularly high. These statistics, however, may be misleading because the term "sociopath" has frequently been used loosely to refer to anyone manifesting antisocial behavior. A 1961 paper by Earle and Earle (8), which demonstrated a higher incidence of sociopathy in a maternally deprived population than in non-maternally-deprived psychiatric controls, included no statement of how the authors defined sociopathy. As they did not include a borderline personality category, one might wonder whether borderline personalities were included in the sociopathy category—the distinction is sometimes difficult to make. To date, there has been to my knowledge no attempt to look specifically at the incidence of early maternal loss in a borderline population, although both Bowlby (4) and Mahler (7, chapter 16) have theorized that severe character defects such as those seen in borderline patients are often the outcome of early maternal deprivation or difficulties in resolution of the separation-individuation phase (which may be related to actual loss).[1]

Although the Gunderson and Singer paper was concerned largely with the adult borderline patient, I believe that their criteria can also apply to child and adolescent borderline patients. This paper reports an attempt to explore the history of single or repeated significant periods of separation from mothers or other significant caretakers in a population of child and ado-

The author wishes to thank the Ministry of Correctional Services for allowing data to be collected on wards, the Psychology Department of Oakville Reception and Assessment Centre for analysis of data, and Dr. Mary Konstantareas for suggestions on data analysis and revision of the manuscript.

The opinions expressed herein are those of the author and do not reflect the views or policy of the Ministry of Correctional Services.

[1]Bowlby does not use the term "borderline," but in his paper on childhood mourning he repeatedly emphasized his belief that inability to deal with angry feelings over loss of the mother results in a variety of different pathologies including extreme and prolonged detachment, use of splitting as a defense mechanism, and severe depressive reactions, all of which are characteristic of the borderline personality.

lescent borderline patients (defined by the Gunderson and Singer criteria). These data are compared with similar information from two control populations.

METHOD

Borderline patients were diagnosed by the six criteria employed by Gunderson and Singer (1). It is my opinion that a history of brief psychotic episodes and/or looseness in unstructured situations (e.g., projective testing) with intactness in structured situations are necessary criteria for the diagnosis of borderline personality. In young children, the intensity of affect is sometimes difficult to assess. However, the other criteria are generally applicable and become even more so as the children reach adolescence.

The patients were seen by me in routine clinical assessments in three different consultation settings: a child and adolescent department of a large psychiatric institute, a preschool day treatment center, and an assessment center for juvenile delinquents in the province of Ontario.

One of the two control populations consisted of nonborderline children and adolescents referred to me for assessment and day-care patients known to me. The charts of both of these groups were reviewed. This population was selected to control for severity of illness. The other control group consisted of delinquent adolescents who were not referred for psychiatric assessment—presumably a somewhat healthier group than those referred. These adolescents represent a nonspecific "character disordered" population. Information on this group was sought from the case managers who were most knowledgeable about each adolescent's background.

There were 14 patients diagnosed as borderline and a total of 68 controls. The subgroups of the control populations break down as follows: 1) 45 psychiatric controls (12 psychotic, 33 nonpsychotic) and 2) 23 nonpsychiatric (i.e., delinquent) controls. The mean age of the borderline patients was 10.9 years for boys (N=10) and 12 years for girls (N=4) (range=5–15 years). The mean age of boys in control samples (N=48) was 11.2 years and of girls (N=20), 11.1 years (range=3–16 years). Accurate placement of these families on a socioeconomic scale was not possible with the available data. My clinical estimate of the families I knew personally would put most in Hollingshead and Redlich (10) social classes III, IV, and V, with 1 borderline family and 3 control families in class II.

Data were gathered on the borderline and control populations with respect to history of separation from mothers or significant caretakers. Separation from fathers was not included unless the father was the significant caretaker. Separation was defined as removal of the child or lengthy absences (greater than 3–4 weeks) due to illness of the mother or caretaker. As there was difficulty in obtaining information about separation due to maternal illness, the bulk of the separations reflect removal of the child or loss of mother or caretaker. Adoption with placement within 1 month after birth was not considered a separation. Once this information was obtained, all separations were divided into those occurring from birth to age 5 and those from ages 5 to 10, reflecting Bowlby's theoretic view of more and less vulnerable periods.

RESULTS

The data, presented in table 1, were analyzed by means of chi-square tests. Those children who had not yet had their 10th birthdays were excluded from the analysis of separations between ages 5 and 10.

Comparison of the total borderline patient sample to the total control sample makes it evident that the history of early but not late separation is greater in the borderlines ($p<.01$). The same applies in comparing the borderlines to the psychiatric controls. Because of the possibility that the borderlines represent a less severely disturbed subgroup on a continuum from neurosis to psychosis (11), borderlines were also compared with psychotic controls. Again, a history of early separation was significantly more frequent in the borderlines.

The adolescent borderlines were compared separately with psychiatrically referred delinquents ($\chi^2=7.2$, $p<.01$) and non-psychiatrically-referred delinquents ($\chi^2=11.59$, $p<.1$), and the same preponderance of increased early separations appeared in the borderline group. Both of these control groups contain a significant number of characterologically disturbed individuals. The incidence of early separations in these delinquents is quite comparable to that found by Glueck and Glueck (11) in a population of delinquents.

The mean age at the time of the first separation was 9.6 months for the borderlines, with a range of 3–30 months, and 13.8 months for the controls, with a range of 1.5–36 months. These differences were not significant.

DISCUSSION

The finding of an increased incidence of early separations in borderline patients supports Bowlby's statements about the critical effect of early disruption of the primary bond. They also lend weight to Mahler's notions regarding the part played by failure to resolve the separation-individuation phase of development in the etiology of the borderline personality, if we may assume that actual separation interferes with the process.

These findings have not generally been noted in other writings on borderline patients, and one wonders if those studies included large numbers of character-disordered individuals who might not have fulfilled the Gunderson and Singer criteria. Many of the controls

[a]$p<.01$.

fall into a group that will ultimately be designated character-disordered, and it is clear that the incidence of early separations in this group, although elevated, is not nearly as high as in the borderline population. In fact, there is a tendency for this group to experience more separations as they age, some of which are related to removal from their natural homes because of uncontrollable behavior.

Because many of the borderline children manifest hyperactivity and learning disabilities, one would suspect that genetic and constitutional factors might be important variables in the production of the borderline picture. In fact, Masterson (3) suggested that most of the mothers of his borderline subjects were themselves borderline personalities. Although Masterson sees the mother's pathology as contributing to her difficulty allowing separation, one could also postulate that genetic or constitutional factors in the child may produce a vulnerability that makes the child overreact to experiences of separation, thereby reinforcing the mother's tendency to fear separation from the child.

The fact that a significant number of the borderlines were adopted raises further questions about genetic predisposition. Some people have, in fact, suggested that a high percentage of all illegitimate children are the product of incestuous unions.

One wonders if children who had multiple placements were constitutionally very difficult to manage and, therefore, subject to more frequent foster home placements. Consistent with this possibility is the fact that many of the adopted children were not placed until several months after birth—a somewhat unusual situation and one which raises the possibility that, even as infants, they might have had either physical or behavioral anomalies.

An obvious weakness in this study is the lack of validation of independent diagnoses. Although the Gunderson and Singer criteria, if adhered to carefully, allow reasonable consistency in the selection of cases, there is still room for disagreement in the interpretation of some of the criteria. The small sample size is the other obvious defect and would point to the need for a replication of this study that takes both factors into account.

In conclusion, the present study provides experimental evidence for the theoretic role of disruption of the early infant-mother bond in borderline pathology.

The Development of an Acute Short-Term Inpatient Child Psychiatric Setting: A Pediatric-Psychiatric Model

BY MOHAMMAD SHAFII, M.D., ANN MCCUE, R.N., M.S., JOHN F. ICE, M.D., AND JOHN J. SCHWAB, M.D.

The authors describe the establishment of a unit for children that emphasizes the integration of the pediatric model of acute, short-term inpatient care with the psychological and developmental perspective of the psychiatric model. Of the 145 children admitted during the first year, more than 33% manifested aggressive or hyperactive behavior and 25%, depression or suicidal behavior. Eighty-five percent were discharged to their homes or previous residences after an average length of stay of 24 days. The authors suggest that similar units established in children's hospitals or general hospitals could help meet the urgent need for acute inpatient psychiatric care of children in this country.

THE MENTAL HEALTH needs of children and youth in this country are in a stage of crisis. According to the 1969 report of the Joint Commission on Mental Health of Children, "We are providing care to only one-third of our children who are in serious need of attention" (1, p. 5). Since then, with the decline in federal funding for mental health services, this situation has deteriorated further. In 1972 the Group for the Advancement of Psychiatry reported, "When the community mental health centers were originally set up, it was stipulated that all ages be served. Nonetheless, most of the initial community mental health centers did not and do not provide facilities to serve children" (2, p. 112). Although 71 million people (33% of the total population) are under 18 years of age, only a disproportionately small percent of our mental health resources are used for this group. Studies by Berlin (3), Adams (4), and Rexford (5) all verify that mental health services for young people are grossly neglected.

From antiquity to the present time, in many societies children have been perceived and treated in ambivalent and distorted ways. De Mause (6) has described the hair-raising and heartbreaking historical trends in the neglect and maltreatment of children throughout the ages. Legitimate and illegitimate children have been killed for many reasons including crying too much or too little, not being perfect in appearance or size, and for being female. Child labor and other protective laws did not reach humanitarian standards even in the United States until recently (7). Although reforms have corrected many abuses, our ambivalence toward children is expressed overtly by neglect and child abuse and covertly by the incarceration of emotionally troubled children in county jails, their long-term hospitalization in dilapidated institutions, and negligence in creating humanistic, short-term inpatient psychiatric facilities for them.

INPATIENT PSYCHIATRIC CARE FOR CHILDREN

Residential Model

Some states do not have any inpatient psychiatric facilities for young people (1, p. 6). Most of the states with long-term psychiatric inpatient facilities for children do not have acute, short-term inpatient services. Under various names, often categorized as "residential settings," the orphanage model for long-term custodial care of children and youth is still the basis of psychiatric care in most public hospitals in this country (8, p. 2246). The residential model places emphasis on screening procedures to ensure that the new patient fits the milieu. It is not uncommon for a child to wait 3–6 months for admission screening, and according to the Joint Commission report only 1 out of 10 children screened is eventually admitted (1, p. 6). Many children stay in such facilities 1–3 years; the average stay is 1–18 months. The emotional impact of the child's long-term separation from family, neighborhood, and school needs careful scrutiny. After all, a 9 or 10-year-old child who is hospitalized for 1 year has spent about 10% of his or her life away from home. Following the child's discharge from the hospital, it may take

Received May 27, 1977; revised Oct. 25, 1977; accepted Dec. 19, 1977.

a long time for him or her to find a place within the family again.

Pediatric-Psychiatric Model

The pediatric-psychiatric model emphasizes the integration of the pediatric model of efficient, acute, short-term inpatient care with the psychiatric model of intensive individual psychotherapy, family therapy, group therapy, milieu therapy, school, art, and activity therapies. The strength of such a program rests on its immediate responsiveness to a crisis situation and rapid admission of the child to the hospital—with preparation but without delay. There should be either no waiting list or a very short one. According to an NIMH survey, the median length of stay in state and county mental hospitals for young people under age 18 is "considerably longer" than the length of hospitalization for persons of all ages (72 days versus 41 days) (9, p. 4).

There is a 33% to 66% shortage of psychiatric beds for children and youth (reference 10 and an unpublished paper by J. R. Whittinghill), although "there are more than 100,000 unnecessary hospital beds across the country" (11, p. 2). Could some of this unused bed space be converted to acute, short-term inpatient psychiatric units for children and youth?

Psychiatry is moving into the mainstream of medical practice. The creation of pediatric-psychiatric units within children's hospitals or general hospitals along with other special units, such as the high-risk nursery, intensive care unit, burn unit, and the pediatric-adolescent unit, is essential for the total care of children. In a pediatric-psychiatric unit all of the necessary diagnostic assessment, therapeutic intervention, and discharge planning can be done concomitantly. The average stay should not exceed 3–4 weeks. From the beginning, the treatment plan should emphasize reintegration of the child with his or her family. The cost of such special units and the occupancy rate should be similar to those of other special units in the medical and pediatric settings.

THE LOUISVILLE PROGRAM

The Bingham Child Guidance Clinic, established in 1913, is the fourth oldest child guidance clinic in the nation. It is the outpatient facility of the Child Psychiatric Services, University of Louisville School of Medicine. For many years the staff of the clinic felt a need for an inpatient child psychiatric facility to provide care for emotionally disturbed children who could not be managed in the outpatient setting.

Setting

Norton-Children's Hospitals' futuristic structure encompasses Norton Hospital with beds for 300 adults, Children's Hospital with 156 beds, Norton Psychiatric Clinic with beds for 36 adults, and the Bingham Child Guidance Clinic. In 1975 one of the 8-bed pediatric units in Children's Hospital was designated for the care of emotionally disturbed children. This unit was named the Ackerly Child Psychiatric Service in honor of S. Spafford Ackerly, former chairman of the department of psychiatry and director of the Child Guidance Clinic for more than 30 years.

The 8-bed unit contains approximately 2,000 square feet and 7 rooms. Two large bedrooms accommodate 4 patients each, and 2 rooms have single beds. A multipurpose room functions as a recreation, dining, and family room. Another small room is used as a family visiting room; on occasion, for diagnostic and treatment purposes, the parents stay overnight in this room and participate in their child's daily activities. An additional room serves as the office for the medical records and as a staff conference and consultation room.

Staffing

To provide an efficient, economical inpatient unit for children, the inpatient and outpatient services were integrated. For example, the child psychiatrist in charge of the inpatient program also supervises and leads a team that provides outpatient services. Child psychiatric faculty, fellows and residents, psychologists, a clinical specialist nurse, and social workers provide services for both the inpatient and outpatient units. Nursing staff and child care workers not only take care of the children on the unit but also accompany them to the classroom and assist the teacher and art therapists.

A Child's Day in the Hospital

Children are seen regularly 3–5 times per week in individual, group, or family therapy. They spend 2 hours per day in a one-room country-style school located in the outpatient facility. A special-education teacher, paid by the county school system, evaluates the child's educational level, develops an individual learning plan using educational materials from the child's home school, and acts as a liaison person to facilitate the child's reentry into the home school. The children receive credit from their home school systems for attendance in the hospital school program. In addition, the daily schedule calls for 2 hours of creative and expressive art therapy in the art therapy studio adjacent to the classroom. The children use the adult psychiatric inpatient gymnasium for 1 hour of planned recreational activity per day. A Red Cross van takes them on weekly outings and to community activities.

In contrast to the practices of many other child psychiatric units, parents usually visit their children daily for 1 hour, at times in the presence of the staff. We encourage these frequent visits in an effort to involve the parents actively with the child's treatment program and to develop healthier attitudes toward the child and each other.

After discharge many of the children are followed by the same therapist for 3–6 months or longer on a week-

ly or biweekly basis. Continuity of care and active follow-up play a significant role in further stimulating the healing process within the child and the family.

Patient Population

During the first year 145 young people (approximately 20% of the outpatient population) were admitted to the inpatient unit. There was an almost equal number of boys and girls. The patients ranged in age from 2–16 years; 43% were 12–16 years old; 39%, 6–11; 14%, 4–5; and 4%, 2–3 years old.

Diagnoses

Thirty-six percent of the hospitalized children manifested unmanageable behavior such as aggression, uncontrollable and impulsive behavior, or hyperactivity. Seventeen percent had psychophysiologic disorders such as anorexia nervosa, asthma, cyclic vomiting, enuresis, encopresis, diabetes, and seizure disorders associated with behavioral disorders. Sixteen percent had psychoneurotic disorders; the majority of them were depressed. About 10% of the children were given the diagnosis of schizophrenia, infantile autism, or other forms of childhood psychosis. Ten percent were admitted because of suicide attempts. Six percent had organic brain syndromes, mental retardation, or other psychopathology; and 5% were suffering from child abuse.

Outcome

During the first full year of the unit's operation, 82% of the 145 children admitted were discharged to their homes or previous residence; most of them continued to receive outpatient follow-up care in the Bingham Child Guidance Clinic and other community agencies. Eighteen percent required placement outside of the home, but only 2 patients (1.5%) were placed in a long-term state psychiatric facility. Eleven patients (about 7.5%) were readmitted for further assessment or treatment on a short-term basis.

The occupancy rate was 122%; 2–3 extra beds were needed to help meet the demand. The average length of stay was 24 days; the median length of stay in state and county mental hospitals for patients under the age of 18 is 72 days (9, p. 4). Thus the patients in our acute treatment unit were removed from their homes for relatively brief periods of time. Further, this short period of hospitalization obviously reduces the cost. Many hospitals and departments of psychiatry have not developed child inpatient psychiatric services because they usually cost more than adult units. Our experience shows that the cost of the short-term inpatient child psychiatric unit was similar to that of adult inpatient psychiatric units and special pediatric units in this area.

CONCLUSIONS

In our experience the successful outcome of the acute inpatient child psychiatry program is based on the following:

1. Freedom from the traditional residential model.
2. Creation of a pediatric-psychiatric model with emphasis on the integration of the immediate response of pediatric practice with the careful psychological and developmental perspective of the psychiatric model.
3. Integration of outpatient and inpatient resources to provide continuity of care rather than the traditional division.
4. Recognition that inpatient care of children is only one small phase of the therapeutic process.
5. Effective and efficient emergency service in the outpatient setting to assess the child's need for immediate hospitalization.
6. Immediate response to the need for hospitalization rather than long and cumbersome screening procedures and waiting lists.
7. Active outpatient treatment and follow-up with the same therapist for consolidation and enhancement of therapeutic gains.

Similar pediatric-psychiatric models established within children's hospitals or general hospitals and managed by the child psychiatric staff could respond to the urgent need for acute inpatient psychiatric care of children and youth in this country.

Adolescents' Adjustment to Chronic Hemodialysis

BY ATARA KAPLAN DE-NOUR, M.D.

The author compares the adjustment of 18 adolescents on chronic hemodialysis to that of 63 adult patients on hemodialysis. The adolescents tended to comply less well with the medical regimen, their vocational rehabilitation was significantly lower, and their social activities were more restricted. The adolescents suffered more from the changes in body functioning and appearances. They were more hostile and overtly aggressive but seemed to have fewer psychiatric complications and, especially, less suicidal ideation. The author suggests that chronic disease is especially difficult for adolescents to handle because it creates stress in areas already problematic for this age group.

THE LITERATURE on the reactions of adolescents to chronic disease is still limited. One problem in their adjustment relates to adolescents' narcissism, which makes them vulnerable to disfigurement and loss of function as well as fearful of injury and/or pain caused by the disease or by treatment. The second problem area is that of alienation. Disease and/or hospitalization causes the adolescents to feel different from others, and they become alienated from their peer group. Sick adolescents increase the anxiety of their peers, who often react with rejection, further increasing their alienation. The third problem area is the increase in adolescents' ambivalence about dependency-independence. Some adolescents solve this ambivalence by regressing to passive and often cooperative behavior. Others try to master their surroundings and fight the medical regimen to the extent of harming themselves.

The advance of chronic hemodialysis as a routine method of treatment enabled us to study a large population of chronically ill patients. In our studies, just under 20% of the patients were adolescents (aged 14 to 19). The aim of the present report is not to highlight the problems of chronic hemodialysis but to concentrate on the reactions of adolescents to chronic disease; the reactions of adolescents will be compared to those of adults undergoing identical treatment. Such a comparison will enable us to determine more clearly whether adolescent patients are indeed different from adult patients, and it may promote understanding of the sources of their special problems and delineate therapeutic interventions.

Received June 13, 1977; revised Aug. 9, 1977; accepted May 2, 1978.

Dr. Kaplan De-Nour is Associate Professor, Department of Psychiatry, Hadassah University Hospital, P.O. Box 499, Jerusalem, Israel.

METHOD

The adolescent group included 18 patients 14 to 19 years old, 10 girls and 8 boys. None of the adolescents was illiterate and about two-thirds had more than elementary school education. Two other age groups were taken as comparison groups: group 1 included 28 patients, 10 women and 18 men aged 20 to 34, and group 2 included 35 patients, 15 women and 20 men aged 35 to 49. The level of education in the two comparison groups was much lower: group 1 contained no illiterate patients but only 50% had more than an elementary school education. In group 2 this percentage dropped to 23%, and 29% of the patients in this group were illiterate.

All of the patients were observed as part of a predictive study on the influence of personality on adjustment to chronic hemodialysis. They were interviewed for the first time before dialysis began and were followed up 6, 12, 24, etc., months after commencement of dialysis. In each follow-up, patients' adjustment was assessed. Assessment of compliance with the diet was based on biochemical data gathered from the patients' charts. Vocational rehabilitation referred only to the number of hours per week of work or study; these data were gathered from patients, nurses, and social workers. Patients' psychological condition was assessed by clinical interviews. Details of the method of predialysis and follow-up interviews have been described previously (1, 2).

RESULTS

None of the adolescents or patients in the comparison groups refused the predialysis interview although they knew that psychiatric research was one of our aims. The interviews with the adolescents, however, were difficult; they were withdrawn, some shy and others sullen. They usually did not talk spontaneously and preferred not to discuss their disease and previous treatments or the upcoming treatment—only 2 girls were overtly anxious and 2 boys inquired about the mechanical aspects of dialysis. On the other hand, the majority of the older patients talked a lot and discussed their disease and previous medical treatments spontaneously and often at length and discussed the

prospects of chronic dialysis from many aspects. The behavior of the adolescents in the follow-up interviews also differed from that of the other patients: the adolescents were usually overtly angry, much more so than the other patients. They expressed anger at the medical staff, at their families, and often at fate.

Table I summarizes various aspects of adjustment to dialysis. The difference in compliance between the adolescents and the comparison groups did not reach statistical significance yet there was a tendency toward less diet abuse in older patients; half of the adolescent group and only a quarter of group 2 abused the diet.

The adolescents' level of functioning decreased much more than that of the comparison groups even before dialysis, and the vocational rehabilitation of the adolescents at follow-up was significantly poorer than that of the comparison groups. Those considered to have achieved vocational rehabilitation worked more than half-time (or were in school). The majority of patients who did not meet this criterion did not work at all.

Unlike the adults, the adolescents were inclined to discuss at length their problems in social activities. Thirteen of the 18 adolescents reported marked decrease in social activities, which they usually did not attribute to physical malbeing. As far as we could ascertain, only 1 of the adolescents had heterosexual social activities. The patients in the comparison groups talked much less about social activities and reported some but no great decrease, which did not seem to disturb them.

The information gathered in the follow-ups about patients' psychological condition is presented in three categories: "none," meaning that no psychiatric complications were observed at any of the follow-ups or that there were only minor symptoms; "moderate," meaning that moderate depression and/or anxiety was observed in at least one follow-up; and "severe," meaning that either moderate depression and/or anxiety was permanent or severe in at least 1 follow-up, and/or that psychotic symptoms were observed. The difference between the adolescents and the comparison groups did not reach statistical significance. However, a tendency was found—the percentage of patients with severe psychiatric complications increased with age. Suicidal ideation was significantly less frequent in the adolescent group and increased with age.

A few words should be added about the adolescents' problems in other areas. The adolescents often discussed bitterly the decrease in or lack of urination. They also complained more than the adult patients about their appearance, e.g., about the pale yellow tinge of their skin. While on dialysis their relations with other patients, including other adolescents, were limited. They talked little to other patients or to nurses, and they seemed to sleep or try to sleep more than the adult patients.

DISCUSSION

The adjustment of the 18 adolescents in our study to chronic hemodialysis was different from that of adult patients. In some aspects of adjustment the differences did not reach statistical significance, but trends could be observed; the adolescents' compliance with the diet was poorer than that of the adults, and the adolescents had fewer and less severe psychiatric complications. The adolescents also had a significantly lower frequency of suicidal ideation. We would like to suggest that the adolescents' tendency to have fewer psychiatric complications is related to the finding that they were overtly angry and often verbally aggressive.

The adolescents were found to do significantly less well than the comparison groups in vocational rehabilitation. This difference is striking considering that the

adolescents had more education and none of them were unskilled workers, factors which promote rehabilitation. Adolescents' social activities were also more limited than the adult patients'; their alienation from their peer group was severe, and they suffered greatly from these changes. Body image problems were much more prominent in the adolescent group.

In summary it can be said that the reactions of adolescents to chronic disease (chronic hemodialysis) are indeed different from the reactions of adult patients. We would like to suggest that these differences are caused by the fact that the stresses of chronic disease which adolescents have to handle lie in areas that are already problem areas because they involve the tasks of adolescence. Consideration of the psychological meaning of injury or illness (3) supports this suggestion. The ill person has a sense of responsibility for the damage, and, in addition, adolescents still have the remains of magical thinking and are prone to displace guilt and to feel guilty about their disease. Illness also means separation from family and friends. Adolescents' ambivalence about their families has often been described, and attaining emotional independence is regarded as a major task of adolescence. Furthermore, normal adolescents feel a strong need to belong to their peer group and not to feel different. Moore (4), who studied patients with malignant disease, expressed the opinion that feeling different is more stressful for adolescents than the threat of death. Disability affects future plans, and learning to plan is considered one of the main tasks of adolescence. Illness and disability cause a feeling of inadequacy, which is often a problem for normal adolescents, as well as the feeling of personal rejection that often accompanies disability. Weinberg (5), who studied suicidal thoughts in physically ill adolescents, found that in boys these thoughts were indeed directly connected to the physical disease and accompanying feelings of inadequacy. In girls, suicidal thoughts were connected to the interpretation of disease as rejection.

Illness and disability often mean or produce sexual problems, and developing one's sexual role and identity is a main task of adolescence. The last point Hamburg (3) mentioned is that disease leads to increased hostility, and the normal adolescent's problems in handling increased aggression have been mentioned by all writers.

All of the problems that have been mentioned in relation to the psychological meaning of disease and disability are even more extreme in the chronic dialysis situation where the frustration of drives and their derivatives is prominent, body image problems are extreme, and life is machine dependent.

One of the requirements for achieving good adjustment to chronic hemodialysis is the capacity for partial regression (6). We believe that adolescents, who have to handle their own ambivalence and struggle about dependency-independence in a situation that is overwhelmingly dependency producing, cannot achieve this delicate balance of partial regression. They use total regression, which results in poor vocational rehabilitation. The inability to handle the normal task of planning for the future while disabled increases the tendency to regress.

A combination of factors seems to be responsible for the abuse of the medical regimen: total regression leading to lowered frustration tolerance, acting out of independence against the adult world, including the medical team, and the need to deny being different from the peer group may all lead to noncompliance.

It seems, therefore, that the regression found in the adolescents is one of the factors responsible for their poor compliance and poor rehabilitation. At the same time, it is believed to be the reason for the comparative absence of psychiatric complications—adolescents express their aggression directly instead of handling it by projection or introjection.

The present findings raise the question of what can be done to improve adolescents' adjustment. It seems that nephrologists also believe that chronic hemodialysis is no way of life for adolescents and prefer kidney transplant as treatment for these younger patients. Transplants were performed on 14 of the 18 adolescent patients (78%) and only 19 of the 63 adult patients (30%). Transplantation is by no means a cure, but some of the stresses are reduced, especially the problems of dependency.

We doubt whether psychotherapy can be of great help to the adolescents. We have found psychotherapy with chronic dialysis patients extremely difficult (7). The prospects seem gloomy indeed, in light of the difficulties of psychotherapy with adolescents, as stated, for example, by Lecker and associates (8): "Psychotherapy with adolescents has come to be known as being difficult, frustrating and unsatisfactory for both the adolescent and the therapist." We would like, however, to suggest that the set-up of treatment could and should be modified to decrease the stressfulness. Any change that would decrease the dependency and increase the adolescent's feeling of mastery and adequacy would reduce the stress and might thus prevent total regression. We therefore agree wholeheartedly with those (9) who recommend special units with staff specially skilled for handling young people.

Juvenile Firesetters: Do the Agencies Help?

BY STUART FINE, M.B., AND DON LOUIE, M.D.

In an attempt to find out what was being done for juvenile firesetters in their metropolitan community the authors reviewed the records of the local fire marshal, juvenile court, and psychiatric clinic. They found that the various agencies involved with 69 juveniles over a 3-year period were unable to coordinate their efforts and were largely unsuccessful in controlling the firesetting. Because the families of firesetters seem to have many other social problems, the authors recommend early inpatient assessment and possible referral to foster homes or residential treatment settings for juvenile firesetters.

IN RESPONSE TO the Provincial Minister of Health's expression of renewed concern about fires set by juveniles, we attempted to find out what was being done for firesetters in our community, a metropolitan area with a juvenile population of about 653,000. We started out with the impression that working with the child in his or her family setting was not effective. Several studies (1–3) have found that children who often set fires and who are assessed by psychiatrists show evidence of a great deal of psychopathology, that other members of their families are often also disturbed, and that firesetting is seldom the only or the presenting complaint.

Much has been written about the psychodynamics of firesetting (4), but very little has been written about management. Although it is not a frequent presenting symptom for referral to child psychiatry clinics, firesetting can cause great economic loss as well as morbidity and mortality.

In a survey of 20 cases Vandersall and Wiener (1) described three subgroups. In the largest subgroup, composed of 9 children, many were infantile, impulsive, and clearly deviant; several of these children also demonstrated severe retardation and developmental deviations. Macht and Mack (5) noted intrapsychic turmoil and chaotic functioning in the families of 4 adolescent firesetters. These studies cited the unavailability of fathers, especially at the time of the firesetting.

In a large survey of 60 juvenile firesetters, Lewis and Yarnell (2) stressed the aggressive component in firesetting, but much of the earlier literature stressed the erotic component. Lewis and Yarnell also pointed out the frequency with which sexually immature adolescent boys working in pairs are found among firesetters. This group seems to be trying to find social acceptance through such exploits. Older adolescents, however, seem to act alone and seem to be even more difficult to treat. In a survey of the attitudes of 300 urban adults toward children who set fires, Winget and Whitman (6) showed that only one-third thought that mental health professionals might be of use to firesetters. Several suggested punishments like "burning him so he'd know better," "calling in a policeman to give him a good scare," and "whipping him and talking to my minister about him."

METHOD

To find out how juvenile firesetters were assessed and managed in our community we met with representatives from the fire marshal's office and from the juvenile court. They stated that these children and their families were very difficult to involve in programs to change their behavior. We noted that there was partic-

0002-953X/79/04/0433/03/$00.40 © 1979 American Psychiatric Association

ularly poor coordination of services for the child who sets fires and his or her family among the different agencies. The approach of the fire marshal's office was to "scare the children so that they would stop."

At the fire marshal's office we examined the records of all reported cases of firesetters aged 5–16 years from 1971 to 1973. We found 78 cases, 26 of which had been referred to the juvenile court. We obtained permission to go to the court to examine the records of those cases, which showed that 11 youngsters had been referred from the juvenile court for psychiatric opinion. We then obtained permission to look at the psychiatric reports.

DATA

Sixty-five fires were set by 36 juvenile firesetters in 1971; 18 fires were set by 11 firesetters in 1972; and 87 were set by 31 firesetters in 1973. The population of metropolitan Vancouver included 636,600 juveniles aged 5–16 years in 1971 and 652,900 in 1973. No census figures are available for 1972.

The 78 firesetters included 9 who set fires in more than 1 year. We thus have data for 69 firesetters. Four of these were girls. Twenty-seven of the juveniles set fires on their own and 44 operated in groups (2 did both solo and group firesetting). Fifteen were over 12 years of age. Twenty-six (37.7%) were referred to the juvenile court, and 11 (15.9%) had psychiatric assessments. Two were referred to a residential treatment center. Twenty-three firesetters were involved in school fires; the others were involved in home, car, railroad car, and lumber fires.

Of the 26 adolescents referred to the juvenile court, 9 were placed on probation, 5 had a "stay of proceedings," and 2 were not brought for a court hearing at all. The remaining 10 were not followed by the juvenile court at all. The reason for referral to the court was seldom the firesetting alone but complaints such as running away from home and "incorrigibility."

According to the psychiatric histories of 11 of the juveniles, 7 were from broken homes and 6 had parents with severe psychopathology, including suicide, homicide, psychoses, and alcoholism. The children themselves were suffering from learning disabilities manifested in school failure, depressive reactions, and family adjustment problems. Three were mentally retarded. Referral for psychiatric assessment was related to such behavioral difficulties as running away from home and to school difficulties rather than primarily to firesetting. All 11 psychiatric referrals had been previously admitted to a general hospital for at least one accident, such as a fracture or accidental ingestion of poison.

Two case histories may help to emphasize the diversity of the symptoms associated with firesetting and the difficulties psychiatrists and other helping professionals may experience in trying to help these children and their families. Both of these cases were reported to the fire marshal's office and were known to probation services.

CASE REPORTS

Case 1. A, an 11-year-old boy, was referred for psychiatric evaluation after setting fire to a car outside the school from which he had recently been expelled. He had been to the psychiatric clinic 2 years previously because he was making slow progress at school and his parents had difficulty in disciplining him. He had difficulties with reading and writing and for 3 years had been in a special class for children with learning disabilities. He also suffered from primary enuresis. He had been evaluated by several agencies and professionals and had been found to have an overall IQ on the WISC of 76 (verbal, 71; performance, 86).

A was the third-born in a family with 4 children; he had 2 older brothers and a younger sister. His father had been unemployed for more than a year at the time of the assessment and was known to drink heavily. A's mother was talkative and circumstantial but well-meaning. A's siblings also had had academic and behavioral problems.

A's developmental milestones were all delayed. According to his parents he was a happy and contented infant and toddler, but he became difficult to manage when he went to school.

The clinic's records showed that A was always pleasant and cooperative when seen individually but that in a group setting he became disruptive and aggressive. His parents were ineffectual in controlling his behavior, and his father was often out of the home because he went drinking at the local pub. All of the members of the family expressed anger by hitting, by developing somatic symptoms, or by running away (one brother had run away twice).

A tutor, a worker from a social welfare agency, a family service agency worker, and staff from the psychiatry clinic had all been involved in A's treatment. Despite all the intervention, A had been expelled from two schools in quick succession, and he set fires. His mother had initially resisted suggestions about residential treatment but finally agreed to let him go to a residential treatment center. We heard that he stopped setting fires while there.

Case 2. B, a 14-year-old boy, was referred for psychiatric evaluation because he threatened to assault his mother and had broken some of the furniture in the house. He was suspected of setting about 10 fires in his neighborhood over a period of 9 months. Before his referral he had refused to go to school for a year. He had been taking a correspondence course for 3 months.

B had been adopted at the age of 10 days. He had an adopted sister 2 years younger than he. His adoptive father was a taciturn man who had irregular hours at his job. His mother was a tense woman who had difficulty in controlling the behavior of her very tall 14-year-old son and rather large 12-year-old daughter. There were no members of the extended family in the province.

B was described as a difficult baby from the time of adoption. He became particularly difficult at 21 months when his sister was adopted. He showed quite marked separation anxiety when sent to kindergarten. At the age of 9 he was referred to a child psychiatrist and was given dextroamphetamine for "minimal brain dysfunction." There was little response to amphetamines. He was then referred to a special

education clinic, which he attended once a week for 4 months. His behavior improved. After 3 months in high school he stopped attending school and spent long periods of time in his room. He refused to leave the house.

The psychiatric record stated that B was a tall (6 feet) 14-year-old who was withdrawn and suspicious of the interviewer. He seemed to have a poor understanding of the interview situation. However, on intelligence tests he scored in the average range.

B and his family were seen weekly over a period of 4 months. Thioridazine, 25 mg, t.i.d., was prescribed. He admitted to setting several fires but would not elaborate on how he felt before, during, or after the setting of these fires. He was suspicious throughout his contact with the therapist. Two residential facilities refused to consider him because he had set fires and they felt they could not "take the chance." He was eventually placed in a facility that placed great emphasis on outdoor activities. The therapist thought B had borderline personality integration, and at times he was frankly psychotic.

The people who dealt with B seemed to have doubted that this well-meaning youth had set so many fires. The fire marshal's office and the patient's family did not inform personnel at the child psychiatry clinic about further firesetting during treatment. B's firesetting ceased in the residential treatment center.

DISCUSSION

The two cases cited illustrate the long history of difficulties that seem to be typical of juveniles who repeatedly set fires. They also illustrate that in some families removal of the child from the home environment for at least a short period of time seems to be necessary to stop the maladaptive behavior, even though removal of the child from the home setting goes against prevailing social work policies. The parents in most of these families were found to be inconsistent in disciplining their children.

The psychiatric reports of the 11 cases reviewed confirmed the findings of other workers that many complaints and symptoms other than firesetting were reported. For example, several children had frequent accidents, which might reflect a lack of supervision in the home.

The agencies that dealt with these children were unable to coordinate their efforts. Not all of the firesetting reported to the fire marshal's office was recorded there. There was minimal intervention when a child firesetter referred to the juvenile court was placed on probation. At best, the probation officer, would see the child once a month, and very little change would occur in a child's behavior and interpersonal relationships.

These children are difficult to assess and treat, and their families seem to be difficult to reach. Unless active efforts are made to intervene, repeated firesetting occurs and tragedies ensue. Fras (7) suggested very directive instructions to parents. If the parents are unable to control the firesetting after obtaining help, other caretakers should be considered. Six months of unsuccessful therapy should be the most allowed. Family therapy for "loosely linked" families may be difficult (8), and individual therapy in these cases seems to be of very limited value. An inpatient evaluation should be obtained and subsequent foster home placement or residential treatment should be seriously considered. "Treatment" of this behavior disorder in the community seems to be particularly unsuccessful.

BRIEF COMMUNICATIONS

The Mini-Mental State Test and Computerized Tomography

BY LUKE TSAI, M.D., AND MING T. TSUANG, M.D., PH.D.

In order to evaluate the clinical usefulness of the Mini-Mental State (MMS) test, the authors had 63 patients complete the test after undergoing computerized tomographic (CT) scans of the brain. Patients with positive CT scans scored significantly lower than those with negative CT scans. Further analysis showed that cerebral atrophy was more closely related to cognitive impairment than focal cerebral lesions only. The authors conclude that the MMS can discriminate organicity in some instances but that further refinement and modification of its subtests are needed for maximum usefulness.

COMPUTERIZED TOMOGRAPHIC (CT) scan of the brain is a noninvasive neuroradiological technique for diagnosing intracranial lesions and dementia (1-3). However, this technique is costly and generally follows a clinical diagnosis of suspected organic disorder of the brain. The clinical diagnosis of organic brain syndrome basically depends on the findings of the mental status examination regarding impairment in orientation, memory, and other intellectual functions (4).

There are standard psychometric tests to measure cognitive ability; the most widely used are the Clinical Test of Sensorium, the Weschler Adult Intelligence Scale, and the Bender Gestalt Test. However thorough these tests may be, they all require a great deal of time to administer, making them impractical in certain clinical situations, such as testing elderly patients or patients with dementia syndrome (5). Thus there is need for an expedient clinical method of measuring cognitive capability that can identify those patients who are likely to have organic brain syndrome.

The Mini-Mental State (MMS) Test, developed by Folstein and McHugh (6), is a short series of questions testing orientation, registration, attention and calculation, recall, and language. Advocates attest to its high degree of validity and reliability in identifying three distinct psychiatric disorders: organic dementia, uncomplicated affective disorders, and depression with cognitive impairment (7).

We have undertaken to evaluate the usefulness of this test by comparing the results of the MMS with findings from CT scans of the brain. We hope to determine whether the MMS can predict organicity and also discriminate among types of organic conditions of the brain.

METHOD

Subjects

The 63 patients in our study group were selected from patients consecutively referred to the radiology department of the University of Iowa Hospitals from November 30 to December 15, 1976. These patients were referred for CT scans of the brain from the departments of neurology and psychiatry of the same medical center. In most cases suspected organic brain syndrome prompted the referral.

Because the MMS involves reading and writing, patients with poor cooperation, motor-sensory aphasia, paralysis of the arm on the dominant side, severe impairment of vision and hearing, or impairment of consciousness due to stupor and coma were excluded. Ac-

Presented at the VI World Congress of Psychiatry, Honolulu, Hawaii, Aug. 28-Sept. 3, 1977. Received Oct. 11, 1977; revised Dec. 5, 1977; accepted Jan. 9, 1978.

cording to these criteria, 20 patients were excluded before we concluded the selection process with 63 subjects.

Procedure

The CT scans were performed using the Ambrose method (8). The determination of ventricular size and degree of enlargement followed methods established by Huckman and associates (9). The radiologist who assessed the CT findings was aware of the purpose of our study but had no knowledge of the individual cases of patients participating in the study.

Within 24 hours of the CT scans one of us (L.T.) administered the MMS to each of the 63 patients. He had no knowledge of the CT findings and scored the MMS tests independently.

Although the entire test contains 11 items and generally requires no more than 10 minutes, the test is not timed. Detailed instructions for administering the test have been provided by Folstein and McHugh (6). The maximum possible score is 30, and according to Folstein and McHugh, who used a selected group of patients to study the validity and reliability of the MMS, the mean score for patients with dementia was 9.7; depression with cognitive impairment, 19.0; and uncomplicated affective disorder, depressed, 25.1. The mean score for a control group of normal elderly persons was 27.6.

After the CT scans were completed and the MMS administered, the 63 subjects were divided into 2 groups based on the results of the CT scans. Group 1 included the 32 patients with negative CT scans and group 2, the 31 patients with positive CT scans. In order to be judged positive, the CT printout had to show evidence of cerebral atrophy and/or focal lesions. Focal lesions include tumor, hematoma, abscess, infarction, and subarachnoid hemorrhage. According to the criteria of Huckman and associates (9), cerebral atrophy is diagnosed if 1) the ventricles are larger than 15 mm but cortical sulci are 5 mm or less, 2) the ventricles are larger than 15 mm and cortical sulci are greater than 5 mm, or 3) the ventricles are 15 mm or less but the cortical sulci are greater than 5 mm.

Table 1 shows the distribution of the 63 patients according to CT findings and clinical diagnosis.

Group 2 was further subdivided into 2A and 2B. Subgroup 2B included the 18 patients whose positive CT scans resulted from cerebral atrophy with or without focal lesions, while subgroup 2A included the 10 patients with focal cerebral lesions only. Three subjects originally in group 2 were excluded because the ventricular size could not be measured due to compression of the ventricles by tumors.

Comparisons between groups 1 and 2 and between subgroups 2A and 2B were carried out using a t test for two means, Pearson correlation coefficient, and chi-square with Yates correction; $p<.05$ was considered to be statistically significant. The mean total scores of each group were compared, as were the mean scores on individual subtests.

RESULTS

The difference between mean total scores reached a statistically significant level ($p<.01$) when group 1 was compared with group 2 (26.4 ± 5.6 versus 20.4 ± 8.3). Group 2 scored lower on all of the subtests, but there was not a statistically significant difference between the 2 groups on the registration subtest. The tests of orientation, attention and calculation, recall, and language showed significant differences between the 2 groups (see table 2).

There was a significant difference in mean total scores ($p<.05$) between patients in subgroups 2A and 2B (25.3 ± 5.4 versus 18.0 ± 8.6) (see table 3). Patients in subgroup 2B scored significantly lower than those in

subgroup 2A on the subtests of orientation and recall, but the subtests of registration, attention and calculation, and language did not discriminate between the 2 subgroups.

COMMENT

The MMS test offers clinicians a quick, easy-to-administer measurement of cognitive functions. We have tried to determine its value and efficiency as a screening process for CT scans. Definite trends were observable. Group 1, the patients with negative CT scans, had significantly higher mean total scores and significantly higher mean scores on all subtests except registration than did group 2, the patients with positive CT scans. The mean total score for subgroup 2B, patients with cerebral atrophy (with or without focal lesions), was significantly lower than that for subgroup 2A, patients with focal lesions only. On the subtests of orientation and recall, the mean scores of subgroup 2B were significantly lower than those of subgroup 2A.

In order to determine whether findings of cognitive impairment were primarily caused by cerebral atrophy rather than focal lesions alone, we compared the results from group 1 with those from subgroup 2A. The comparison showed that there was no statistically significant difference between the mean total scores or between the mean scores of any of the subtests. That is, there appeared to be no significant difference in performance between patients with negative CT scans and patients with only focal lesions. These results strongly suggest that diagnostically subgroups 2A and 2B are two distinct groups.

Shapiro and associates (10) found that in testing attention and calculation, the Serial Sevens Test could not differentiate organic from functional mental disorder. Hinton and Withers (11), on the other hand, found that brain syndrome did significantly reduce patients' scores on this test. In our investigation there was a significant difference between the mean scores of group 1 and group 2 only when the scores of the Serial Sevens Test were combined with the scores from the Spell "World" Backwards Test. These results suggest the need for further investigation of the clinical merits of this subtest.

Within the subtests of language, 100% of the patients from group 1 and 90% from group 2 could correctly name a watch and a pencil; 94% of all patients could perform the reading task correctly (reading and obeying the statement, "Close your eyes"). The value of these items is dubious.

The Copy-Design Test, a modification of the Bender-Gestalt Copy Design Test, has a reputation for detecting organic brain syndrome (12). In our study, this was the only test question within the language subtest that differentiated between groups (correct copying in 94% of group 1 versus 55% in group 2; $p<.01$).

Patients with negative CT scans performed better than those with positive scans on the Sentence Repetition Test, although there was no significant difference between mean scores. The other two questions testing language faculties (writing a sentence and following a three-stage command) elicited no significant differences between groups. The value of these subtests must also be questioned.

Hinton and Withers (11) reported that the correlation between age and scores on clinical tests of sensorium was not high. Our investigation revealed that the correlation between age and total MMS score was not significant in group 1, whereas there was a significant negative correlation in group 2 ($r=-.426$, $p<.02$). Further analysis of group 2 showed that there was no statistically significant negative correlation in either subgroup 2A or 2B. However, in subgroup 2B there was a trend toward a negative correlation ($r=-.402$, $p<.10$). These results indicate that in patients with negative CT scans or focal cerebral lesions alone, the total MMS score will not be affected by age; however, in patients with cerebral atrophy with or without focal lesions, there is a trend toward a negative correlation between total MMS score and age. Although Folstein and McHugh (6) reported that the total MMS score difference was not due to age, the influence of age on MMS scores needs further investigation.

Hinton and Withers (11) also noted that there was a direct or indirect relationship between the scores of clinical tests of sensorium and the length of schooling but that this relationship had little predictive value. In our study there appeared to be a significant difference ($p<.05$) in length of schooling between groups 1 and 2 (50% versus 23% had more than high school education). However, further analysis comparing group 1 and subgroup 2A with subgroup 2B showed no significant differences. Our study appears to support Hinton and Withers' observation.

In summary, it appears that the Mini-Mental State Test has some clinical value for diagnosing organic brain syndrome. We found that the total MMS score and the subtests of orientation and recall were useful for discriminating between cerebral atrophy and focal cerebral lesions. However, on the basis of our findings, we recommend that future study seek to further refine and modify various test questions.

Urinary Excretion of Dimethyltryptamine in Liver Disease

BY STUART A. CHECKLEY, B.A., B.M., B.CH., MICHAEL C.H. OON, B.SC., PH.D., RICHARD RODNIGHT, B.SC., PH.D., D.SC., MARIAN P. MURPHY, ROGER S. WILLIAMS, M.D., AND JAMES L.T. BIRLEY, M.B., CH.B., D.P.H.

The urinary excretion of N,N-*dimethyltryptamine (DMT) was higher in patients with severe liver disease than in normal subjects. This difference remained significant when patients with all grades of hepatic encephalopathy were excluded. Patients with liver disease whose mental states were normal excreted amounts of DMT similar to those of patients with a hospital diagnosis of schizophrenia.*

N,N-DIMETHYLTRYPTAMINE (DMT) is a hallucinogen that occurs normally in human urine in very small quantities (1). We have twice reported that its excretion is increased in some patients with psychotic illnesses (2, 3), although these observations are disputed (4). The meaning of any increased excretion of DMT in psychotic illness is uncertain, although superficially it lends credence to the hypothesis that DMT is involved in the pathogenesis of some psychotic symptoms (5, 6). To examine the significance of any increased excretion of DMT in mental illness, a search has been made for other conditions in which the excretion of DMT might be similarly raised. The liver contains enzymes sufficient for the synthesis of DMT (7) and for its degradation. It might be expected therefore that in liver disease the urinary excretion of DMT would be raised, partly because its metabolism might be impaired and partly because freshly synthesized DMT might be released from damaged liver cells. If endogenously formed DMT of extracerebral origin causes psychotic symptoms, then patients excreting abnormal quantities of DMT should experience psychotic phenomena, provided that the patients are sufficiently alert.

The recognized psychiatric effects of acute liver disease are those of an acute organic reaction (8). The severity of this reaction may be measured by a clinical rating of the level of consciousness on a 5-point scale that has been validated against EEG findings (9). This grading system will indicate those patients who are too drowsy to describe any mental effects of altered metabolism of DMT. The central question raised in this paper is whether patients with liver disease who have normal mental states excrete abnormally large quantities of DMT.

METHOD

Urine collections (24-hour) were made from patients admitted to a specialized liver unit. The patients had a wide range of liver diseases, most of which were both severe and acute. Patients with a raised blood urea concentration were excluded.

Similar collections were made from a group of normal volunteers who have been described previously (1) and from a group of patients with a Maudsley Hospital diagnosis of schizophrenia, made by using the British Glossary of Mental Disorders (10). We derived standardized diagnoses from the Present State Exami-

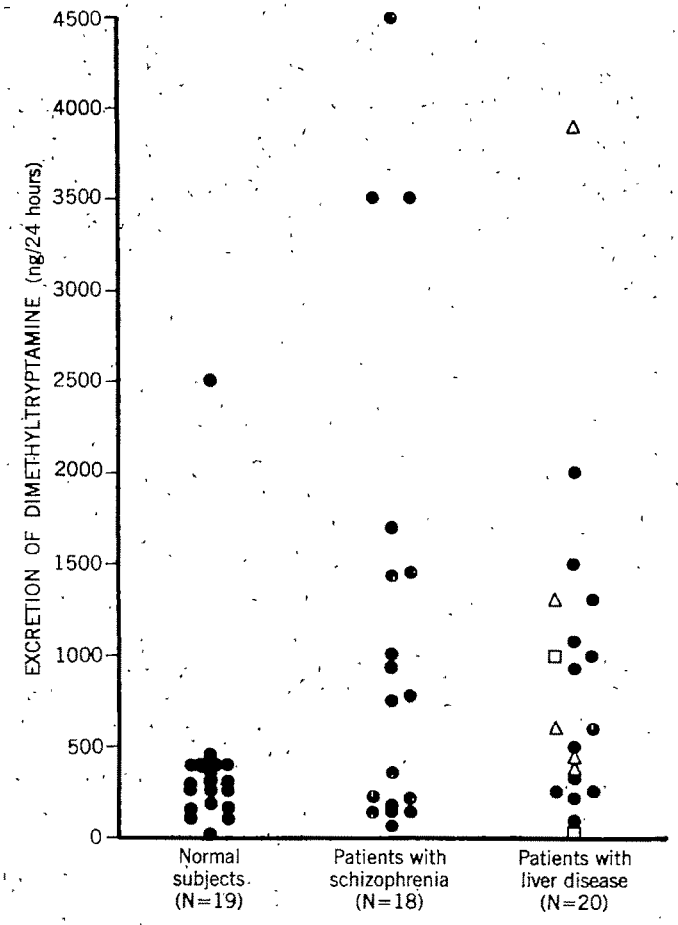
nation (11) using the Catego program: S+ (N=14), P+ (N=2), and P? (N=1) and D+ (N=1). These patients form part of a larger clinical study that will be reported separately (3). Urinary DMT was determined by using a specific gas chromatographic method (12).

The Mann-Whitney Statistic and the Spearman Rank Correlation Coefficient were used for statistical analysis, as individual values for each biochemical measure were not normally distributed.



RESULTS[1]

The patients with liver disease (N=20) were well matched with the schizophrenic patients (N=18) and the normal subjects (N=19) for age and for renal function. The fact that they had a different sex ratio should not have affected the results, since there was no relationship between sex and the excretion of DMT within the control groups.

The excretion of DMT was higher in the patients with liver disease than in the normal subjects ($p<.01$). This difference remained significant ($p<.05$) after exclusion of patients with all grades of hepatic encephalopathy. The excretion of DMT was similar in the patients with all grades of hepatic encephalopathy. The excretion of DMT was similar in the patients with liver disease and schizophrenia (figure 1). Although the difference between schizophrenic patients and the normal patients failed to reach statistical significance, the present finding that 10 out of 18 patients with a diagnosis of schizophrenia excreted more than 500 ng of DMT in a day closely replicates our previous report that 20 out of 42 patients with a diagnosis of schizophrenia excreted detectable DMT (2). The detection limit of that method was 500 ng/24-hour urine collection.

Results of the routine liver function tests demonstrate the severity of the illnesses that were studied. Mean plasma concentrations for albumin, total bilirubin, alkaline phosphatase, and aspatate transaminase were 29 g/liter (range, 15–41), 203 nmol/liter (range, 37–480), 577 IU/liter (range, 94–2750), and 402 IU/liter (range, 61–2500), respectively. No significant relationships were found between the excretion of DMT and values for individual liver function tests; rather it seems that the excretion of DMT is raised across a wide range of different forms of acute liver disease. The raised excretion of DMT cannot be attributed to drugs since the difference between patients with liver disease and the normal subjects remained significant ($p<.05$) after we excluded patients who were receiving drugs that might affect the excretion of DMT. These drugs included steroids, other immunosuppressive therapy, and insulin but not antibiotics or vitamins. Changes of diet and sterilization of the gut have already been shown to have no effect upon the excretion of DMT (1). Three of the patients studied had taken paracetamol overdoses. Independent psychiatric evaluation in each case of overdose excluded the possibility of a functional psychosis. In view of the hallucinogenic properties of DMT it is interesting that no patient in the present series described either hallucinations or illusions.

FIGURE 1
Median Urinary Excretion of Dimethyltryptamine[a]

[a]Grade of encephalopathy of patients with liver disease: ●, grade 0; △, grades I and II; and □, grade IV.

DISCUSSION

We have shown that the excretion of DMT was higher in a group of patients with liver disease than in a group of normal subjects. This difference remained significant after exclusion of patients with hepatic encephalopathy. The increased excretion of DMT in the patients with liver disease was similar to that seen in patients with a hospital diagnosis of schizophrenia.

It seems most likely that the raised excretion of DMT in these patients reflects raised blood concentrations and not merely an increased renal clearance. DMT readily crosses the blood brain barrier—euphoria has been reported within minutes of an intravenous injection of DMT (13). If the patients with liver disease have raised concentrations of DMT in their

[1]Tables are available on request from Dr. Rodnight.

blood, it is likely that they will also have raised concentrations of DMT in their brains; however, their mental states appeared unaffected by such concentrations of a known hallucinogen. None reported hallucinations, and although some showed features of hepatic encephalopathy, there was no relationship between the excretion of DMT and the grade of encephalopathy. The present series suggests that an increased extracerebral production of DMT has no detectable effect on the mental state of a patient with liver disease; however, there may be an interaction between the effect of DMT and the neurochemical effects of liver disease.

The increased excretion of DMT in patients with liver disease and a normal mental state has to be compared with the observation that the parenteral administration of DMT causes hallucinations. It may be that DMT is only hallucinogenic when present in larger quantities than are found in patients with liver disease and schizophrenia. This explanation is supported by the observation that the excretion of DMT in subjects receiving hallucinogenic doses of DMT (13) is approximately 100 times greater than that found in our psychotic patients (2).

Although the present study suggests that the extracerebral production of DMT in these quantities has no effect on a patient's mental state, the possibility remains that DMT is formed within the brain and influences mental phenomena. One experimental strategy for manipulating the metabolism of any DMT that is formed within the brain is the administration of monoamine oxidase inhibitors. These drugs increase the excretion of DMT (1), probably by inhibiting its metabolism. It is therefore of interest that when these drugs have been given to drug-free schizophrenic patients under double-blind controlled conditions, the patients have reported no symptomatic change (14–17). We conclude that it may be useful to study the relationship between DMT and psychosis by examining other situations in which the production of endogenous hallucinogens may be increased.

Adjustment of a Group of Vietnamese People to the United States

BY A. JOE VIGNES, M.D., AND RICHARD C.W. HALL, M.D.

The authors collected data on 50 Vietnamese families living in Baton Rouge, Louisiana, by individual and group interview questionnaire. They also used interviews of all of the Vietnamese people who came to the local community mental health center and studied the records of the center and other local social agencies for sociodemographic data. They define a number of specific sociological stresses encountered by Vietnamese refugees but conclude that basically these people are adjusting well without losing their cultural identity.

A GREAT DEAL has appeared in the lay press concerning the adjustment of Vietnamese people to the United States. The scientific literature remains largely silent on issues of this transcultural adjustment. We undertook the prospective study described here in an attempt to evaluate the psychiatric and social factors affecting the adjustment of Vietnamese refugees in the United States.

METHOD

We randomly selected 50 Vietnamese families, representing a total population of 114 individuals, from a list of newly settled Vietnamese in Baton Rouge, Louisiana. All 50 of the families initially surveyed agreed to participate in the study after the nature of the study was explained. The study design consisted of four elements.

Social Adaptation Questionnaire

One individual from each of the 50 families participated in a two-hour structured interview followed by a one-hour informal interview. All of the data thus obtained were used to develop a formal questionnaire to rate the overall adjustment to American society of all the subjects (N=114).

The seven investigators of the survey team (three Vietnamese and four Americans) initially chose 300 questions. These 300 items were presented to an individual from each of the 50 families. The responses were analyzed for clarity of meaning when translated into Vietnamese, subject acceptance, and lucidity of the translated concept. One hundred items were chosen for inclusion in the final questionnaire. Fourteen percent of the questions involved the area of self-image; 14%, religion; 12%, community relations; 12%, future expectations; 10%, relationship to authority; 9%, family relations; 7%, adjustment while in Viet Nam; 6%, finances; 6%, political orientation; 5%, marital relations; and 5%, sexual adjustment.

A 7-point discriminative scale ranging from positive adjustment (+3) through 0 to a negative adjustment (−3) was devised. The survey team subjectively rated each question. Questions felt to have the highest positive discriminatory adjustment value were rated +3 (i.e., "I feel happy in the United States"), and neutral items were rated 0 ("I approve of people who drink socially"). Items indicating the poorest adjustment were rated −3 ("I do not find it easy to make friends with Americans"). Items between these extremes were rated +2, +1, −1, and −2. Twenty-four percent of the questions had a value of +3 or −3; 23%, +2 or −2; and 23%, +1 or −1. Thirty percent of the questions were considered neutral and had a value of 0.

Social Adjustment Scale Questionnaire

Five Vietnamese college students administered a bilingual (Vietnamese-English) questionnaire to the 50 families in their homes. The questions were asked and answered in Vietnamese. The data from these questionnaires were analyzed by computer, and total adjustment scores were assigned to each respondent. These scores were then correlated with sociodemographic variables.

Social Survey Data

Sociodemographic data were collected from local social agencies, such as the community mental health center, state and private psychiatric institutions, schools, and law enforcement agencies. Agency utilization data, arrest records, and medical and psychiatric information were gathered for all of the Vietnamese in the Baton Rouge area.

Psychiatric Evaluation

One of the authors (A.J.V.) interviewed all of the Vietnamese people who came to the local community mental health center during a one-year period.

DATA

Twenty-three percent (N=114) of the total Vietnamese population of Baton Rouge participated in the study. Sixty percent of these individuals were men; 58% were married. Ages ranged from 19 to 77 years with a mean age of 35.6 and a median age of 37. Eighty-three percent of the group had completed secondary school, and 60% had received at least a year of university training. Forty percent of the population stated that they were currently involved in some type of educational program. Twenty-two percent of the men interviewed had practiced a profession when they were in Viet Nam, but only 6% functioned in a professional capacity in the United States.

Four percent of all of the Vietnamese families in the area were receiving welfare (compared with 9% of all families in the area). During the study 6 minor traffic violations involving a Vietnamese were recorded. No Vietnamese had been arrested for any of the 6 categories of crime surveyed, which included rape, homicide, driving while intoxicated, theft, assault, and disturbing the peace. School officials reported language barriers as the major area of educational concern. The children presented no behavior problem in the schools. Educators felt the initial passivity and withdrawal of the Vietnamese children had abated markedly during their first year in school. No peer problems or difficulties with school authorities were reported for the Vietnamese children.

Scores on the social adjustment questionnaire for our sample of 50 families ranged from a low of −47 to a high of +70, with a mean score of 25.5 and a median of 24. Subjects scoring +25 or above were placed in the high adjustment group, and those scoring +24 or below were placed in the low adjustment group. Eight percent of the respondents received negative adjustment scores (mean negative rating, −17.2). Ninety-two percent of the respondents received positive adjustment scores (mean positive rating, +29.2). High and low adjustment group data were analyzed using a two-tailed chi-square test for significance of differences. Data were analyzed for differences of adjustment, determined by age, religion, income, education, and marital status. No significant differences were defined except for income. The high-income group in the United States was significantly less well adjusted than the low-income group. All of the subjects showing negative adjustment scores (N=10) had been high-income professionals in Viet Nam (income greater than $10,000) and also fell into the high-income United States group (income greater than $10,000).

The records and interviews at the local community mental health center and the records of state hospitals and private psychiatrists in the Baton Rouge area revealed 5 cases of schizophrenia during the study year. Three of these patients had been diagnosed as schizophrenic while in Viet Nam. All of the patients were men and were diagnosed as having paranoid schizophrenia. Two patients, 1 male and 1 female, had had an acute nonschizophrenic psychotic reaction that responded within 10 days to phenothiazine treatment. Two women who made suicide attempts were diagnosed as having acute psychoneurotic depressive reactions. Two men were diagnosed as having psychotic organic brain syndrome. One of these patients had viral pneumonia, and the other had acute hepatitis. The confirmed diagnosis and treated incidence and prevalence data are shown in table 1.

TABLE 1
Treated Incidence and Prevalence of Mental Illness in a Population of 488 Vietnamese Living in Baton Rouge, Louisiana, During 1976[a]

Diagnosis	Number of Cases	Treated Incidence[b]	Treated Prevalence[b]
Schizophrenia, paranoid type	5	.4	1.02
Acute reactive psychosis	2	.4	.4
Organic brain syndrome	2	.4	.4
Reactive depression	2	.4	.4

[a]Total treated incidence=1.64/1,000 individuals/year; total treated prevalence=2.25/1,000 individuals/year.
[b]Cases/1,000 individuals/year.

DISCUSSION

In 1975 Segal and Lourie reported to Rear Admiral S.G. Morrison that psychological shock and depression were the major psychiatric effects among Vietnamese relocated to Guam. They suggested a five-part program to meet the psychological and social needs of these people. Segal (1) reported that this program was followed, for the most part, by the authorities responsible for resettlement.

Our study suggests that the Vietnamese have adjusted well in the United States. Their treated incidence and prevalence of major psychiatric disorders was no higher than for the population at large. The 10 subjects in this study exhibiting poorest adjustment (8%), who were free of major psychiatric disorders, were in the highest socioeconomic strata in both Viet Nam and the United States. Loss of professional role and identity seemed to be major factors complicating their adjustment. In each case, the individual perceived extensive loss in both social and professional status. As a group they found it difficult to associate with other Vietnamese and were unwilling to socialize with the newly developing "upper class" of Vietnamese-Americans. This group reflected more on past losses and were more uncertain about the future than any other subgroup; they were also the least able to accept a socially forced change of occupation.

The difficulties predicted by the lay press for Vietnamese refugees adjusting to the American lifestyle have not materialized. Vietnamese children are doing well in school, the refugees have accepted American social norms, and the Vietnamese community has been able to maintain its cultural identity. The major problems reported by our subjects related to unemployment and underemployment. The need to supplement family income has forced many women to seek employment and to change their role in the family structure. The women reported favorably on their new "freedom," but it remains a source of consternation for men, who see it as an erosion of the patriarchal family structure. Recently developing marital discord also represented an important problem.

The major sociological stresses identified in this population were 1) loss of role identity, 2) loss of self-esteem, 3) social isolation secondary to language barriers, 4) local prejudice directed toward the Vietnamese, 5) Vietnamese prejudices directed toward the local community, 6) suspicion of helping agencies, and 7) suspicion of the U.S. government's motivation and intent.

The initial response of the Vietnamese families studied to resettlement in America was one of passivity followed in two to three months by expressions of anger and disappointment, which lasted at peak intensity for another four to six months. Following this phase, adjustment and acceptance increased dramatically. We noted no substantial deculturalization of Vietnamese traditions except for a change in the role of women. The women saw this as a positive change and were anxious to become more assertive.

Peer Review of Group Therapy: Washington, D.C., 1972–1977

BY MARTIN G. ALLEN, M.D.

The author discusses the evolution of psychiatric peer review in Washington, D.C. In its first six years (1972–1977) the Washington Psychiatric Society Peer Review Committee evaluated 146 cases, 23 (16%) of which focused on group therapy. Eight of these cases (35%) were partially or fully denied. Most of the cases involved outpatients with neuroses or character disorders who were treated in combined group and individual therapy. The author presents specific cases illustrating group therapy issues and peer review decisions. He discusses the benefits and liabilities of peer review and emphasizes its importance as a flexible, clinically sensitive, confidential, and meaningful process.

Received Jan. 30, 1978; revised May 8, 1978; accepted June 19, 1978.

Dr. Allen is Chairman of the Group Therapy Subcommittee, Washington Psychiatric Society Peer Review Committee. He is also Director of the Group Therapy Program and Associate Professor of Psychiatry, Georgetown University School of Medicine, 3800 Reservoir Rd., N.W., Washington, D.C. 20007.

THE CONCEPT OF peer review in psychiatry and its actual implementation come at a time of increasing involvement by insurance companies and the federal government in the delivery of psychiatric services as well as greater consumerism in our society. In addition, there is the possibility of national health insurance, with psychiatric coverage. These developments have led to the medical audit as an effort to maintain cost control. The review of psychiatric services by peers is a result of all of these factors.

The APA Task Force on Peer Review has presented a model of peer review for psychiatry (1), including guidelines and methods of implementation. Its statement delineates the objectives of peer review as education of the physician and evaluation of quality, cost, and quantity/utilization. In addition, Sullivan (2) has emphasized the importance of confidentiality.

In Washington, D.C., psychiatric peer review first developed in 1972, probably due to a large population with insurance for psychiatric services and to the federal government's emphasis on accountability and audit procedures. Questions about cases usually come from insurance companies after screening by a psychi-

0002-953X/79/04/0444/04/$00.45 © 1979 American Psychiatric Association

atric consultant. Each case is reviewed by qualified peers who are experienced and understand the nuances and details of specific, specialized clinical problems. A decision is made in each case to accept, deny, or partially accept.

Chodoff and Santora (3) have discussed the Washington, D.C., method of operation and the overall experience with psychiatric peer review. The present paper presents a summary of peer review of all cases involving group psychotherapy in Washington, D.C., in the six years from 1972–1977. Specific cases illustrating group therapy issues and peer review decisions will be presented.

SUMMARY OF GROUP THERAPY CASES

From 1972–1977, 146 cases were referred to the Washington Psychiatric Society Peer Review Committee. Group psychotherapy was involved in 23 of these cases (16%). Of the 23 cases, all but 1 (from a psychiatrist) were referred by insurance companies. There were questions about 19 individual cases, 1 question about billing procedure from a psychiatrist, and 3 cases questioning patterns of care (in which several cases involving a single provider of care are submitted to peer review, with questions raised about a pattern of treatment).

A total of 60 questions were asked regarding the 23 cases, with an average of 2.6 questions per case. Twenty of the cases involved a combination of group and individual psychotherapy. The 3 cases in which group therapy was the only modality involved outpatients, and all of these were fully accepted by the Peer Review Committee.

Eight of the cases (35%) were either partially denied (6 cases) or completely denied (2 cases). A partial denial/approval occurred when some questions about the case were approved but others were denied. In Chodoff and Santora's report of the Washington, D.C., peer review experience from 1972 to 1975, 37% of all questions asked were denied. Thus the percent of denials for group therapy cases in the present study was similar to the overall Washington, D.C., experience. Three of the 8 denials were appealed, but the committee did not find any reason or further evidence to reverse its decisions.

Three of the cases involved inpatient treatment; 18 cases involved outpatients; 1, partial hospitalization (day care); and 1, inpatient and outpatient care. The patients' ages ranged from 8 to 69. Information about the diagnosis showed 12 cases of neurosis or personality disorder, 5 cases of psychosis, 3 cases of adolescent adjustment reaction, and 1 case of childhood adjustment problem.

Over the years the experience of the peer review committee has included a range of issues. There have been questions about patient selection, frequency of sessions, duration of treatment, and billing practices. Some of the issues specific to group therapy involved marathon sessions, rotating therapists, and multiple therapists.

CASE ILLUSTRATIONS

Several cases will be described in order to illustrate the types of questions asked of the peer review committee and the committee's response.

In one case the questions were: Is this marathon therapy? What benefits can be provided? The committee's response was as follows.

> The psychiatrist involved in this case has made clear this is not a "marathon session" in the usual sense of the word where most of the members may be strangers or at least not part of an on-going group therapy, but, in fact, are members of a regular group undergoing psychotherapy.
>
> There are a few well-known Washington area psychiatrists who feel that this procedure of "extended group psychotherapy" is a valuable adjunct to regular group psychotherapy. There are certain constraints which they feel should be maintained. They feel that there should be no more than four such sessions per year and that patients should be in at least once-a-week therapy the rest of the time. The "extended group sessions" should be conducted by the same person (or persons if a co-therapist is involved) who usually conducts the group.
>
> Since the group cannot possibly receive the same degree of attention normally exercised in a group session the hourly fee should be less, probably one-half, and never more than $100 for a weekend type session. There is no evidence to support the idea that extending a session to the point of breakdown of human endurance is therapeutic. The Committee feels that eight hours on a given day is the maximum for which one can expect useful work of this type.

Subsequent cases are often decided by precedents or criteria established in previous cases. The following case is an example.

> This case is concerned with "extended group psychotherapy sessions." The physician in this case documents the psychiatric condition for which he was treating the patient. He also gives clear documentation as to his reasons for the use of extended sessions. He meets the criteria we set forth in a previous case:
>
> 1. The patient was in regular group psychotherapy and in this case also in individual psychotherapy.
> 2. The physician held these extended sessions no more than four times per year.
> 3. On each of the successive days in which the physician held extended sessions, the total number of hours did not exceed 8.

The following is another example of an approved case.

> The problem presented in this case was "Is this an acceptable type of therapy?" The services rendered were described as "Network Intervention Therapy-Marathon Therapy." The therapy referred to is that of a network

treatment of a family in which the two children were diagnosed and billed as patients. The physician conducted five 50-minute sessions on two evenings approximately 2 weeks apart. In these sessions were the patients, all the family members, and all people with whom the patients had contact. The psychiatrist and his staff members conducted several strategy sessions on their own separate from these group network sessions. The psychiatrist charged at the rate of $8.75 per hour per patient. We feel that in this particular case the treatment seemed to be acceptable and also had useful end results in terms of the patients' treatment. We feel that the charges to the patients and their family were reasonable.

The following statement by the committee illustrates a decision of partial denial.

The patient is a 50-year-old married female with a long history of psychiatric care with diagnoses of schizo-affective schizophrenia and/or manic depression. The history supports the provider's summary that this patient is fragile, passive, socially isolated, anxious, and a difficult management problem.

Group therapy was begun to help this patient with her social isolation, feelings of alienation from her family, and as a supportive modality. However, in addition, the patient has been seen, weekly, in one 90-minute or two 45-minute psychotherapy sessions on the same day.

Our answers to the questions are:

1. A 90-minute or two 45-minute sessions in one day are not appropriate in this case. Our recommendation would be for individual sessions of no more than 50 minutes. Sessions more than once a week might be warranted during periods of crisis but once per week sessions should be sufficient for long-term treatment.
2. The committee does feel that weekly group psychotherapy sessions are appropriate. A once-weekly group therapy session would be appropriate, in addition to a once-weekly individual therapy session.

The last two examples are classified as complete denials.

Two child psychiatrists were conducting group psychotherapy with adolescents and each psychiatrist billed the patient separately. Each charged $20 per session. The question was asked: Is this appropriate utilization and appropriate cost?

Group psychotherapy with a co-therapist was found to be an appropriate treatment modality for these adolescents. However, it is not the usual and customary practice in this area for co-therapists to charge full fee, regardless of their training. A single charge is to be made for group therapy with or without a co-therapist. Although this can be billed singly or separately, the total should be within the range of the usual and customary fee for group psychotherapy in the area.

This patient was depressed, mistrustful, and ambivalent in close interpersonal situations and unable to make important decisions. Antidepressant medication was not successful . . . . Individual psychotherapy sessions were then conducted alternately with the psychiatrist and the psychologist. The patient was seen by both therapists individually, by the psychiatrist in group psychotherapy, and by the psychologist in group psychotherapy. In April, for example, the patient was seen weekly by the psychologist in group and in individual sessions and by the psychiatrist in group and individual sessions for a total of sixteen visits. On April 16, the patient was seen four times—once in each of the treatment modalities.

The peer review committee felt the patient was in need of psychiatric treatment. However, the pattern of therapy involving the two therapists and both individual and group sessions did not conform to any recognized treatment pattern and appeared to provide no continuity. This treatment program was not appropriate for this case.

DISCUSSION

Most of the cases with questions about group therapy were fully accepted by the peer review committee; only 2 were completely denied. The percent of complete denials is low, especially considering the fact that insurance companies have a screening procedure wherein questionable cases are reviewed by a nurse, and, if still questioned, they are sent to a psychiatric consultant. Many questioned claims are approved; only those not resolved at an earlier stage are referred to peer review.

How can we interpret the fact that few cases were denied? Is it reflective of loose standards, a lack of understanding, or a lack of clear standards and guidelines? It should be noted that 35% of the cases were completely or partially denied; this is a sizable percentage. In addition, we on the committee found that when clinicians communicated directly to us (and the chairman maintained confidentiality by deleting all names of persons and places), they felt more free to give complete details, knowing that the information would not be in the files of a bureaucracy. That helped us to understand a case more fully and to appreciate specific clinical decisions. Finally, when the peer review process began, standards and guidelines were not clear. As a result of our experience with peer review, we developed guidelines combining our experiences as clinicians, our experience with the peer review process, surveys of local practice, and recommendations from the APA guidelines. Currently our standards are being used by local insurance companies, and fewer cases have been referred for peer review.

Consequently, case review was not the only activity of the peer review committee. It also worked to develop standards for peer review, length-of-stay criteria for inpatient hospitalization (based on current local practice), and to review a collection of cases when questions arose about patterns of care. Obviously, all of these activities are interrelated.

The peer review process can have beneficial and detrimental results. Peers can review, and sometimes censure, questionable practices. The very existence of peer review serves as a deterrent to questionable clinical or billing practices. It also helps maintain cost control. However, at the same time peer review may inhibit innovation and experimentation with new approaches, combinations, and techniques. It also

becomes a factor in therapy, threatens confidentiality, and may interfere with treatment, especially with paranoid patients, patients involved in divorce cases or other legal proceedings, or patients in highly visible positions of power or prestige.

In conclusion, the three *A*s of modern society—automation, auditing, and accountability—are upon us. It is our responsibility to develop and implement a meaningful peer review process that is sensitive, flexible, and understanding of the realities of clinical issues. Through its decisions, peer review establishes standards of patient care. It is the clinician, not the bureaucrat, who must develop a realistic and viable peer review process—one that demonstrates confidentiality, accountability, and the highest quality of professional care.

Medicaid Audit: Crisis in Confidentiality and the Patient-Psychiatrist Relationship

BY HARVEY J. SHWED, M.D., SEYMOUR F. KUVIN, M.D., AND RAVI K. BALIGA, M.D.

The authors describe their experience with a routine Medicaid audit and discuss the damage such a procedure can do to the trust between psychiatrists and patients, confidentiality, doctors' reputations, transference reactions, and patients' own emotional states. The authors point out that these crucial issues have broad implications because of the possibility of passage of national health insurance legislation.

CONFIDENTIALITY is undergoing intensive scrutiny because of the major upheaval in traditional concepts of the patient-doctor relationship in the past decade (1–3). Third-party insurers, whether private or government, armed with computers and data banks, have seemingly insatiable appetites for detailed information about what transpires between doctor and patient in order, they say, to justify the benefits they pay and to be assured that competent medical service has been rendered (4–9). What are the boundaries between the right to know and the doctor's time-honored pledge to patients of confidentiality?

Nowhere is confidentiality more basic to a discipline than in psychiatry and psychotherapy. Our experience suggests the possibilities for destruction of this patient-psychiatrist trust in a routine Medicaid audit of a psychiatrist's practice. (Medicaid is the federal-state program that pays for the health care of 28 million low-income Americans who meet eligibility guidelines for participation.)

Received Oct. 4, 1977; accepted Jan. 9, 1978.

Shwed and Kuvin are also Clinical Assistant Professors, and Dr. Baliga is Clinical Instructor, Department of Psychiatry, New Jersey Medical School of the College of Medicine and Dentistry of New Jersey. Send reprint requests to Dr. Shwed.

MEDICAID AUDIT PROCEDURE

In New Jersey, a Medicaid audit is an investigation of a physician and his or her practice. It is for the most part a routine check of doctors who treat significant numbers of Medicaid-sponsored patients. Medicaid staff limitations prevent the staff from scrutinizing all doctors who see Medicaid patients. They therefore give priority attention to doctors who see a large number of Medicaid patients or whose practice has raised the suspicion of fraud or abuse. We were audited because Medicaid patients comprise approximately 10%–15% of our private group psychiatric practice, which is located in a medical school-affiliated teaching hospital in Newark, N.J.

The Medicaid audit as typified by our experience includes the following:

1. The psychiatrist's office is informed of the impending audit and a mutually convenient appointment

0002-953X/79/04/0447/04/$00.45 © 1979 American Psychiatric Association

is made. The doctor is told that 25 or 30 patient charts will be reviewed the day of the audit and that preselected patients will also be interviewed by the audit team either before or after the formal visit to the psychiatrist's office. The identity of the patients is not revealed until the day of the audit. Members of the audit team who interview physicians in the field are usually not physicians.

2. The team interviews the psychiatrists and asks about such items as Board certification or eligibility, medical school affiliations, and names of other physicians and staff members within the practice.

3. The team asks for the charts of the preselected patients.

4. The team views and reproduces the charts. This procedure is especially important to them because a Medicaid physician at the central office ultimately reviews these patient records. In cases where a doctor is suspected of fraud or abuse, such charts and records serve as evidence for the Attorney General's office.

5. The team also reviews office bookkeeping procedures. Because New Jersey Medicaid will not reimburse psychiatrists for unkept appointments, the audit team searches for deviations from this standard when examining a psychiatrist's records. The audit team asks to examine the doctor's appointment books, presumably to assess the time the psychiatrist devotes to each patient.

6. The auditors, according to what our patients have told us, ask questions relating to a) quality of care patients feel they have received, b) how they like their doctor, c) how much time the psychiatrist spends with them, d) whether they were "prepped" for the interview by their doctor, and e) if they have any complaints about the doctor or his or her practice.

7. The team collects any information doctors offer as documentation of the kind of service rendered to their Medicaid patients. We supplied to the audit team copies of an introductory and orientation brochure we give each new Medicaid patient. The brochure explains our practice policies, provides emergency numbers to call when our office is closed, and indicates our "on call" availability. It also attempts to deal with the issue of unkept appointments, a serious problem in a psychiatric practice and, unfortunately, a characteristic pattern for many Medicaid-sponsored patients. We also supplied our weekly statistics of unkept Medicaid appointments to the audit team.

To document our contention that Medicaid patients receive extraordinary amounts of extra session service and time, we asked every member of our staff to keep a log for one month of the time and effort devoted to our Medicaid patients other than face-to-face psychotherapy sessions.

THE PSYCHIATRIST-PATIENT TRUST

It is difficult for us to conceive of meaningful psychotherapy taking place without implicit and explicit guarantees to the patient that confidentiality will be maintained (10, 11). Under the best of circumstances, patients enter psychotherapy with varying degrees of suspiciousness, resistance, and mistrust, based on their earlier life experiences.

Guarantees of confidentiality are crucial to the special trust between patient and psychiatrist that permits the patient to share increasingly intimate and difficult material with the therapist. For the overly sensitive or frankly paranoid patient any hint that confidentiality has been violated will destroy the therapeutic endeavor. So fragile and yet important to psychotherapy is the concept of confidentiality that, in our opinion, merely the idea that someone might have access to intimate material precludes meaningful psychotherapy from taking place.

On the first day of contact with the psychiatrist, the Medicaid patient signs a form permitting the psychiatrist to receive reimbursement for his or her services, which also gives Medicaid permission to examine and request any and all charts.

> Patient Certification. Authorization to release information, and payment request. I certify that the service(s) covered by this claim has been received, and I request that payment be made on my behalf. I authorize any holder of medical or other information about me to release to the Division of Medical Assistance and Health Services or its authorized agents any information needed for this or a related claim.

It is our belief that the nature of the Medicaid form brings greater pressure to bear on the Medicaid patient than on other patients. Middle-class patients do not have to sign such a form, and, in fact, many of them decide not to sign any insurance form because of the issue of confidentiality. Regrettably, they end up paying for psychotherapy on their own.

Medicaid's "Right to Know"

In New Jersey, 600,000 residents receive Medicaid funds, and the state and federal governments spent $429,577,145 for their health care in 1976. Across the nation, 28 million Americans depend on Medicaid for their health care, at a total cost of $14.7 billion. A program encompassing so many people and such large sums of public money may justly argue that it has not only a right but a responsibility to American citizens to monitor the medical care that they pay for. The executive and legislative branches of government expect it and the general public, whose tax dollars pay for the program, demands it.

Violations of Confidentiality

The act of reading psychiatric patient records by the staff of a geographically distant bureaucratic agency makes a sham of any pretense of confidentiality between a psychiatrist and his or her Medicaid patients. The Medicaid team who conducted our audit were not physicians. They were polite, deferential, and tactful

as they went about their business; nevertheless we shared a deep feeling of having been violated and having in turn betrayed our Medicaid patients.

Our sense of outrage was intensified by the knowledge that the selected patient charts were to be copied and transferred to central Medicaid offices in Trenton where they would be reviewed by the "psychiatric consultant." What would ultimately happen to these copies of our patient records was not made clear.

Medicaid's own policy of guaranteeing confidentiality and promising serious penalties to any staff member found guilty of violating such confidentiality is inadequate for the psychiatrist and his or her patient. In our opinion, merely the act of sharing psychiatric material with "benign" strangers is detrimental to the patient-doctor relationship.

In addition to the symbolic impact that Medicaid's "right to know" has upon the therapeutic alliance, there are more realistic and practical issues. We are less concerned with nefarious deeds perpetrated by "Big Brother" governmental agencies (although the Watergate-related Daniel Ellsberg case comes to mind) than with the inadvertent foul-ups that seem likely to occur when any large bureaucratic organization has confidential data at its disposal. The recent disclosure that names of 48,000 New York State women who had undergone abortions had not been deleted from data transmitted to the National Institutes of Health for a research project is a case in point (12).

PATIENT-PSYCHIATRIST RELATIONSHIPS

Psychiatrist and Staff Anxieties

An audit or examination, no matter how routine and from whatever the source, evokes anxiety in the psychiatrist and his or her staff. In an age of increasing government involvement (e.g., potential national health insurance, PSROs, and mental health advocacy), psychiatrists and their physician colleagues should be prepared for the onslaught of those carrying "right to know" passes.

The nightmare of every ethical physician is that a government investigating team, which consciously or unconsciously must justify its existence, will be too rigid and literal in interpreting rules or regulations and will fault doctors for not "dotting their i's or crossing their t's." In the case where an investigation leads to an actual indictment, ultimate acquittal is little consolation to the doctor who in the meantime has suffered irreparable damage to his or her professional reputation, days and months of emotional stress, and income lost from his practice and from legal fees.

The Effect of Patient Interviews

One of the charges leveled against a doctor in our state who was ultimately indicted for Medicaid abuse was that he attempted to "prep" his patients for their interview with the team. The Medicaid team, naive about psychotherapy issues and techniques, might therefore view any pre-interview discussions with our patients as an attempt to influence the patient's honest and frank responses to their questions, so when we were informed of the Medicaid audit, we felt constrained not to discuss it with our Medicaid patients. This violates a basic tenet of psychotherapy: that anything and everything relevant to the patient's psychotherapy can and should be discussed.

One psychiatrist, not in our group, told us that after a Medicaid audit interview patients called to warn the therapist that he was "in trouble." No matter how benign the investigation may be or how nonpejoratively it may be presented to the patient, the therapeutic relationship has been injured and, by innuendo, the psychiatrist's reputation has been harmed.

Furthermore, the type, intensity, and stage of transference reactions between the patient and psychiatrist may be interfered with by the audit interview. Likewise, transference may significantly distort the patient's replies to the investigator's questions; patients' responses may be unrealistically glowing and warm when positive or even erotic transference is occurring and unfairly damaging if the patient is working through issues of negative transference at the time of the audit.

The selection of patients who will be interviewed by the audit team does not, to our knowledge, consider the patient's psychological ability to take part in the interview or how the dialogue might be emotionally harmful to the patient. What is the effect of the audit interview on the patient who is fragile and overly anxious, paranoid, withdrawn, reclusive, passive-aggressive, or sociopathic? How do these characteristics influence and distort the replies that are given, especially to a nonmedical, nonpsychiatric investigator? What is the ultimate effect on the nature and future of the therapy and the patient-psychiatrist relationship?

COMMENT

As America moves closer to a national health insurance program, health planners, politicians, and government officials are gaining experience from the current health payment program for the 28 million Medicaid-sponsored citizens in the United States. The majority of psychiatrists in private practice who do not see Medicaid patients will face similar issues if and when they are blanketed into a national health insurance program serving a more universal population.

The overriding philosophical issue, with many diverse practical ramifications, is whether a government-administered health program, which spends large sums of public tax money and insists that it has the right to know in order to monitor quality of care and insure fiscal integrity, can accommodate the need to maintain a meaningful patient-psychiatrist relationship and confidentiality.

The task of dealing with and reconciling these conflicting needs is awesome.

Special Issue of *AJP* to Feature Depression and Alcoholism

A special issue of the *American Journal of Psychiatry* will be published in mid-April 1979. This issue, which will be distributed to all subscribers and is in addition to the regular April issue, will consist of a collection of articles on the subjects of alcoholism, depression, or both. Articles will deal with such topics as the treatment of depression with imipramine and ECT; bipolar illness: factors in drinking behavior; physical activity and plasma cyclic AMP in manic-depressive patients; childhood depression; life events at the onset of bipolar affective illness; psychiatric problems in women at alcoholic detoxification; lithium maintenance; efficacy of drugs and psychotherapy in the treatment of acute depressive episodes; and life events, coping, stress, and depressive symptomatology.

Authors include David Avery, M.D., Jesse O. Cavenar, Jr., M.D., David L. Dunner, M.D., Ronald R. Fieve, M.D., Eric W. Fine, M.D., Evelyn L. CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Excretion of Imipramine and Desipramine in Human Breast Milk

BY ROBERT SOVNER, M.D., AND PAUL J. ORSULAK, PH.D.

Little information is available concerning the excretion of psychotropic drugs, including the tricyclic antidepressants, in breast milk (1, 2). Knowles (3) attributed this lack of data to difficulties in doing studies on nursing women, the complexity of the chemical analyses, and a general lack of interest in undertaking them. In this paper we will present a case report documenting the excretion of both imipramine and desipramine in human breast milk.

Case Report

Ms. A, a 32-year-old mother of two children, presented with the complaint, "I'm afraid of getting depressed again." She had had a depression when she was 26, following the birth of her first child, and at that time required imipramine in dosage of 350 mg/day for a therapeutic response. Once in remission, she continued to take imipramine, 200 mg/day, for 6 years until she became pregnant for the second time.

At 1 month postpartum Ms. A began to experience mild depressive symptoms and sought treatment. She also had a history of hypothyroidism and takes levothyroxine, 0.3 mg/day. She was euthyroid at the time of her reevaluation. She was started on imipramine at bedtime and was taking 200 mg h.s. on the 14th treatment day. She had been nursing her child before the initiation of drug therapy and decided to continue doing so after treatment began. Imipramine therapy was initiated with the collaboration of the child's pediatrician, who examined the infant during the time Ms. A was breast feeding and taking imipramine. No physical or behavioral changes were detected by either Ms. A or the pediatrician. However, on the 16th day of treatment, she agreed to discontinue breast feeding. During these first 3 weeks of drug therapy, Ms. A showed no clinically significant response to imipramine.

TABLE 1
Imipramine and Desipramine Levels in Plasma and Breast Milk[a]

Treatment Day	Hours Since Drug Ingestion	Concentrations (ng/ml)	
		Imipramine	Desipramine
Milk			
16	23	18	29
16	1	29	30
17	9	24	35
17	23	4	17
17	1	12	20
18	10	12	26
Plasma			
22	13	21	41

[a]The patient's imipramine dosage was 200 mg h.s. She discontinued breast feeding on day 16.

On the 16th treatment day Ms. A began to collect milk samples for imipramine and desipramine assays. She collected six samples over a 34-hour period and placed them in her freezer until her blood was drawn. Plasma samples for determination of imipramine and desipramine concentrations were obtained on the 22nd treatment day, 13 hours after the last drug dose, from blood drawn into heparinized Venoject vacuum blood collection tubes. Plasma was separated by centrifugation and stored at −10° C until analyzed. Plasma concentrations of imipramine and desipramine were determined by a modification of the method of Cooper and associ-

ates (4) using a gas chromatograph equipped with a nitrogen detector. Analyses of imipramine and desipramine in breast milk were carried out in a manner identical to that used for the plasma assays. Ms. A gave informed consent to participate in this study.

As shown in table 1, the blood samples revealed antidepressant levels below the therapeutic range of 150–250 ng/ml for imipramine plus desipramine (5, 6). However, quantifiable levels of both imipramine and desipramine were found in the breast milk specimens and the concentrations in breast milk were similar to those found in plasma.

Discussion

In a comprehensive review, Ayd (1) noted only two reports on the excretion of tricyclic antidepressants in human breast milk. In one (7), detectable levels of imipramine were found in the milk of a nursing mother, and concentrations were related to drug dosage. In the other, Knowles (3) reported no detectable drug levels in milk from nursing mothers who had been taking imipramine for up to 5 days. More recently, Ananth (2) reviewed side effects of psychotropic agents excreted in breast milk and concluded that imipramine is present in much lower concentrations in breast milk than in plasma.

Our paper is, to our knowledge, the second report of imipramine excretion in human breast milk and the first to indicate that the demethylated metabolite desipramine is also found in breast milk, both in concentrations similar to those found in plasma.

With respect to other tricyclic antidepressants, Eschenof and Rieder (7) assayed the milk of six normal postpartum women who had received a single oral dose of amitriptyline within 8 days after delivery. Five of these women received 50-mg doses and the sixth received 25 mg. No detectable drug levels could be found in any of the milk samples. Ayd (1), based on results supplied by Eli Lilly & Company, manufacturers of nortriptyline, reported negative findings in serial milk samples from a lactating woman who had been given a single 25-mg oral dose or nortriptyline. We could find no reports concerning the other tricyclic antidepressants, doxepin and protriptyline.

It is most likely that imipramine and desipramine are passively transported into milk along with lipid substances because both drugs are highly lipophilic. This is a common mechanism for the transport of drugs into breast milk (8). Since other tricyclic antidepressants are also lipophilic, they should be transported into breast milk by the same mechanism as imipramine and desipramine. It may be that these drugs appear in milk only after chronic ingestion and that the negative findings for amitriptyline and nortriptyline resulted from the use of single, relatively small drug doses. Knowles' failure (3) to find imipramine may indicate that a period of 5 days of drug ingestion is not sufficient. (Our subject had been taking imipramine for 16 days before milk samples were collected.)

Ms. A's child did not appear to be affected by the ingestion of imipramine and desipramine. However, the levels of these drugs in the mother's plasma were well below therapeutic levels. Since similar concentrations were present in the milk samples, it is possible that even higher concentrations of these drugs may be found in the milk of women who achieve therapeutic levels of imipramine. At these higher concentrations the drugs might have clinically significant effects on nursing infants. In addition, we do not know whether there would have been physiologic or behavioral effects if the infant had been exposed to imipramine for a longer period of time.

Given the current state of knowledge regarding the excretion of tricyclic antidepressants in human milk, it would be prudent to advise nursing women to discontinue breast feeding if they require antidepressant drug therapy. As Rivera-Calimlim (9) noted, even small drug doses may have significant effect on infants because of their greater gastrointestinal permeability (compared to adults) and the immaturity of their drug-metabolizing enzymes, which may result in enhanced drug accumulation.

Multiple ECT: Morphologic Effects

BY MATTHEW MENKEN, M.D., JAN SAFER, M.D., CHARLES GOLDFARB, M.D., AND ERVIN VARGA, M.D.

Memory loss and other intellectual changes may be a prominent side effect of ECT (1). Since it was introduced into clinical practice in 1937, ECT has been recognized by most psychiatrists as an effective therapy for psychotic depressions, catatonic stupor, and other selected clinical conditions. However, because of the possibility of post-ECT amnestic-confusional syndrome and the introduction of psychotropic drugs, ECT has been used less widely in recent years, undoubtedly due in part to the potential medicolegal exposure. Indeed, certain techniques, such as unilateral nondominant hemisphere ECT, have been employed to reduce memory loss. Because subjective memory complaints may persist after ECT, a literature has developed suggesting that ECT is effective because it produces memory loss, i.e., the treatment works by creating brain damage (2). However, the majority of clinicians have opposed this view of ECT, except to the extent that it is analogous to treatment modalities such as pharmacotherapy, which act by inducing biochemical changes that could be labeled "damage" as a matter of rhetoric.

Computerized tomography (CT) is a new neuroradiologic tool that is an extremely sensitive and noninvasive procedure for investigating many neurologic disorders. Essentially, it measures alterations in tissue density and associated displacement and distortion. It is extemely sensitive in detecting hemorrhage and edema, the two pathologic changes most often ascribed to ECT. The administration of 10 ECTs over 45 minutes to a suicidal patient afforded us the opportunity to perform a CT scan before and after ECT in a clinical situation that would be particularly likely to produce an abnormality if such changes were common after ECT.

Case Report

Ms. A, a 30-year-old woman, was admitted to the hospital on Oct. 26, 1977, with the diagnosis of unipolar depression. She had had recurrent depressions for the past 7 years. She had never received ECT. During her current depressive episode she had received imipramine, amitriptyline, and doxepin sequentially in dosages to a maximum of 300 mg/day without benefit, and she became suicidal. The patient said her father was "always depressed" and her mother had been depressed during menopause. An EEG and neurologic examination were normal. All tricyclic antidepressants were discontinued. On Oct. 27, a CT scan was performed (scan time 2 minutes, 10 seconds).

Apart from sulcal prominence, the CT scan was normal. On the next day, the patient was medicated with sodium theopentol and succinylcholine and given 10 ECTs during a 45-minute period by one of us (C.G.).

Three hours after the multiple ECT, a repeat CT scan was performed. No change was observed when the scan was compared with the earlier study. At this time, the patient was amnestic for events during the day before ECT and disoriented to place and time. She also showed restlessness and confusion that resulted in some motion artifact on the second CT scan. This disturbance of the higher intellectual functions gradually resolved, and on Nov. 9 (12 days after ECT) no confusion or objective impairment of memory was detected. The patient's depression had improved markedly, and she was discharged from the hospital.

Comment

Status epilepticus has been shown in approximately one-third of cases to produce on CT scan the succession of brain edema and subsequent brain atrophy (3). Since the edema and atrophy were unilateral on the CT scan when the clinical seizures were unilateral, it is apparent that the pathologic changes depend on the epileptic process itself rather than the secondary effects of the convulsions, such as an hypoxic/ischemic encephalopathy. Thus, it seems appropriate to infer that if the effectiveness of ECT depended on the production of morphologic changes in the brain, the CT scan would be able to detect such changes.

Thus, the absence of any CT changes following administration of multiple ECT in a 45-minute period to a patient who demonstrated the typical post-ECT amnestic syndrome suggests that the basis of the amnestic-confusional syndrome depends on functional subcellular or synaptic changes, and that ECT does not produce hemorrhages or edema in the brain. It is also appropriate to note that if an autopsy showed prominent sulci, this might be mistakenly ascribed to ECT. The possibility that local alterations in vascular permeability contribute to amnesia and confusion is not excluded by the present study; we thought it was not justifiable to subject this patient to an intravenous injection of iodinated contrast material to measure alterations of cerebral blood flow patterns.

Lithium in Chronic Schizophrenia

BY GLENN A. GROWE, PH.D., JOHN W. CRAYTON, M.D., DAVID B. KLASS, M.D., HENRY EVANS, M.D., AND MICHAEL STRIZICH

Recent research indicates that in addition to its well-established effect on manic-depressive psychosis, lithium is helpful for patients with a variety of other disorders, including hyperaggressiveness, depression, and epilepsy (1). Still uncertain is lithium's place in the treatment of schizophrenia. Controlled studies of lithium given alone to schizophrenics have generally found it to be ineffective (2, 3). Anecdotal reports suggest that lithium can occasionally lessen hyperactivity and aggression without modifying the core symptoms of schizophrenia (4). That schizophrenic patients react to lithium differently than affectively ill patients is suggested by reports of increased neurotoxicity in lithium-treated schizophrenics. Shopsin and associates (5) found confusion, memory impairment, disorientation, and reduced comprehension in 11 of 17 schizophrenic patients, even though their blood levels of lithium were maintained at about 0.75 mEq/liter. A general clinical worsening accompanied this toxicity. Cohen and Cohen (6) reported irreversible brain damage in excited schizophrenic patients mistakenly diagnosed as manic who received a combination of lithium and haloperidol. On the other hand, Small and associates (7) obtained favorable results by adding lithium to the regular neuroleptic drug regimen of a group of schizophrenics. Ratings of patients on several variables, including a global rating of severity of illness, showed significant improvement. A toxic reaction to lithium was observed in only 1 of 22 subjects. In view of these conflicting data on lithium's effects in schizophrenia and the uncertainty about its role in treating schizophrenia, we studied the effects of combining lithium with neuroleptic medication administered to a group of chronic schizophrenics. Care was taken to monitor blood levels of lithium and to assess both diagnosis and behavioral ratings.

Method

The subjects were eight inpatients (two men, six women) on the Clinical Investigation Unit of the Manteno Mental Health Center. Six subjects fulfilled the Research Diagnostic Criteria standards for the diagnosis of schizophrenia and two met the criteria for schizo-affective schizophrenia (8). The subjects had a median number of three previous admissions and a median age of 25 years. Subjects gave their informed consent to participate in the study. Patients were admitted to the study if they had failed to respond significantly to medication. Either lithium or placebo was added to the treatment regime in a 16-week double-blind placebo-controlled crossover study. Each treatment period lasted 4 weeks. Neuroleptic medications, including haloperidol, chlorpromazine, and trifluoperazine, were maintained at a constant dosage throughout the course of the experiment.

Incorporated in the design were two lithium and two placebo periods; each lithium period alternated with a placebo period. Lithium carbonate was administered in divided doses totalling 900–2400 mg/day in order to maintain serum lithium levels of 0.5–1.0 mEq/liter. Serum lithium determinations were made twice weekly. Patients were also rated biweekly on the eight manifest behavior scales of the Psychotic Inpatient Profile (9). Ratings were done by staff members who were familiar with the patient. The data analysis included 72 observation days for which both behavioral ratings and lithium determinations were available.

Results

Behavior ratings done on patients while their serum lithium levels were within the normal therapeutic range were compared with those done while their levels were subtherapeutic. A repeated-measures analysis of variance for the various subscales of the Psychotic Inpatient Profile revealed significant improvement in only one of the eight scales, Psychotic Excitement, $F(8, 195)=2.66$, $p<.01$. Ratings of patients on this scale averaged 5.99 for subtherapeutic periods compared with 3.77 for therapeutic-range periods. There were trends toward less seclusiveness and reduced retardation on therapeutic-range ratings. No significant changes occurred in the other scales, including Hostile Belligerence, Paranoid Projection, Anxious Depression, Care Needed, and Psychotic Disorganization. None of these patients showed significant lithium toxicity.

Discussion

The results suggest that adding lithium to a neuroleptic regimen in schizophrenic patients produces a decrease in psychotic excitement. This result raises the question about the presumed specificity of lithium for mania (10), since it does appear to have an effect on certain aspects of schizophrenic behavior, and a

suggests that its effect in schizophrenia may be on one aspect of schizophrenic behavior that is closely related to mania, namely, excitement.

Those scales which tapped behavior more specifically symptomatic of schizophrenia were not affected by lithium. This result is congruent with the anecdotal reports of lithium modifying activity levels but not the primary symptoms in schizophrenia. Lithium may be a useful adjunct to the phenothiazines in the treatment of schizophrenics whose clinical picture includes psychotic excitement.

No significant toxic reactions were seen in the present study. This finding supports the published report (7) that lithium can be combined with neuroleptics and does not pose the increased danger of side effects seen with lithium alone. Further studies may clarify which patient groups are most responsive to a lithium-neuroleptic combination.

Group Psychotherapy as an Adjunct to Lithium Maintenance

BY SAAD A. SHAKIR, M.D., FRED R. VOLKMAR, M.D., SANDRA BACON, M.S.W., AND ADOLF PFEFFERBAUM, M.D.

Traditionally, patients with bipolar affective illness have been considered poor candidates for group psychotherapy; the presence of a manic-depressive member in a heterogeneous outpatient therapy group has been termed "one of the worst calamities that can befall a therapy group" (1, p. 393). There has been general agreement that the character of manic-depressive patients, including those on lithium prophylaxis, makes psychotherapy difficult, even during the euthymic phase of the illness (2). A substantial number of patients will relapse, even those receiving lithium, and a significant minority of patients will remain chronically ill (3, 4). There have been reports of conjoint family and couples group psychotherapy as an adjunct to lithium maintenance (5, 6). In this article we report our experience with a long-term ongoing psychotherapy group composed exclusively of patients with bipolar affective illness who are receiving maintenance lithium therapy.

Received Oct. 28, 1978; revised Dec. 12, 1978; accepted Jan. 2, 1979.

Dr. Shakir is in private practice in Palo Alto, Calif. Dr. Volkmar is Resident in Psychiatry, Stanford University Medical Center, Stanford, Calif. 94305. Group Composition and Format

Fifteen patients (13 men and 2 women, mean age=43.3 years, range=19–63 years) have participated in the group. Diagnosis was established by at least two psychiatrists on the basis of history and mental status examination and was supported by psychological testing. All patients had responded acutely to lithium treatment before participating in the group. The average duration of lithium prophylaxis before entry into the group was 21 months.

Three of the members corresponded to the bipolar type II description of Fieve and associates (7), i.e., they had been hospitalized for depression and had a history of hypomania. The remainder were bipolar type I, i.e., they had a history of hospitalizations for mania and mild to severe depressions. Ten patients had histories of poor adherence to lithium maintenance. Prior to their participation in the group patients were evaluated by the two cotherapists (F.R.V. and S.B., or S.A.S. and S.B.), and the general theory and purpose of group psychotherapy and group format were discussed with them.

The group met for 75 minutes weekly and was con-

0002-953X/79/04/0455/02/$00.35 © 1979 American Psychiatric Association

ducted primarily with an interpersonal, interactional "here and now" approach as described by Yalom (1). Lithium carbonate was dispensed monthly during the final 30 minutes of the group meeting. Lithium levels were maintained in the range of .8–1.2 mEq/liter. Group members were free to discuss specific problems or concerns regarding lithium treatment at any time. The average duration of group treatment was 51 weeks; the mean number of participants per session was 8.2. Generally, members left the group after obtaining full-time employment but continued to attend the group monthly for support and medication. Three members left the group after about 12 sessions; they were given medication follow-up outside the group.

Several common themes emerged during the course of patients' participation in the group. Initially they were skeptical of both the long-term efficacy of lithium prophylaxis and the benefits of group psychotherapy. This seemed to reflect their previous experience with group therapy and their ambivalence about the loss of a sense of well-being that lithium use sometimes entails (8). Participants typically exhibited massive denial of their problems on entering the group and projected responsibility for the efficacy of lithium maintenance onto the psychiatrist while remaining aloof from other group members. After approximately 10 sessions patients became more identified with the group and more committed to it. During this period members became more interpersonally revealing and actively solicited the advice and support of other members. Common problems included concerns about the chronicity of their illness, the threat of recurrence, societal acceptance, and marital and occupational adjustment. Less time was spent discussing medications and more time in interpersonal learning, instilling hope, and imparting information. If a group member began to exhibit signs of either mania or depression, other members would discuss this openly and provide support and encouragement while medications were adjusted as necessary. Individual members gradually began seeking to return to full-time employment and after doing so would return monthly to the group for medication and support.

Outcome

In the 2-year period prior to participation in the group, 10 of the members had been hospitalized for manic or depressive episodes. The group as a whole spent an average of 16.2 weeks a year in the hospital during this period, with mean lithium levels of .53 mEq/liter. Only 5 members were continuously employed during this period. During the 2 years the group has functioned, 3 of the participants have been rehospitalized for affective episodes. The group has averaged 3.2 weeks of hospitalization a year in this time, with mean lithium levels of .94 mEq/liter. Ten members have now been continuously employed for over 6 months. Participants and their families have indicated a more satisfactory interpersonal and social adjustment.

Discussion

Despite the fact that 10 of the participants had histories of poor adherence to maintenance lithium treatment, the rate of recurrence compares very favorably with those reported in follow-up studies of lithium maintenance treatment (3). As in other studies of lithium maintenance, the most common reason for lithium prophylaxis failure was discontinuation of lithium (8); two of the patients who required rehospitalization had stopped taking their lithium several months after terminating their participation in the group. It is difficult to determine whether the relatively high rate of adherence to lithium maintenance we observed reflects the effects of group therapy per se or the close supervision patients received each week; certainly, the modeling of lithium compliance and effectiveness provided by the occasional attendance of employed group members enhanced lithium compliance.

We have been impressed that, contrary to expectation, our group of manic-depressive outpatients could work therapeutically in a homogeneous group. The shared experience of manic-depressive illness and lithium prophylaxis made the occasional episode of hypomania or depression much less disruptive than would have been the case in a heterogeneous therapy group. The same curative factors at work in other therapy groups were seen in this group (1). Such groups may serve as a simple, efficient, and highly cost-effective adjunct to lithium maintenance treatment, especially for patients with a history of poor compliance, and may provide the benefits of psychotherapy to a group of patients generally viewed as poor candidates for traditional therapeutic modalities.

Withdrawal Symptoms After Abrupt Cessation of Amitriptyline in an Eight-Year-Old Boy

BY C. THOMAS GUALTIERI, M.D., AND JEANNETTE STAYE

We recently treated a child who seemed to suffer an amitriptyline withdrawal reaction. The patient developed severe gastrointestinal symptoms when amitriptyline was stopped abruptly, and there was no evidence to suggest a toxic or infectious origin for his nausea and vomiting. This case report suggests that a withdrawal syndrome may occur in children treated with amitriptyline when the drug is stopped abruptly.

Case Report

The patient, an 8-year-old boy, was referred to our clinic because of hyperactivity and problems with drug management. He had been treated with methylphenidate from age 2½ (an unusually early age for such treatment) to 6, apparently with some success. When he was 6, he was placed in a highly structured classroom and did well, so the drug was stopped. When the next school year started, however, he began to have the same problems—hyperactivity, distractibility, disruptive behavior, emotional lability, and sleeping difficulties. Methylphenidate was tried again but only increased his symptoms.

In November, amitriptyline was begun. He appeared to do well on 30 mg at bedtime, and serum levels in December showed 30 ng/ml of amitriptyline and 10 ng/ml of nortriptyline. In early spring, a number of new behavior problems arose—he was irritable and seemed depressed—and the sleep problems recurred. The dose of amitriptyline was raised to 50 mg q.h.s., with no apparent response. He was referred to our clinic at this point.

The boy had no severe medical problems, and his development was normal. His IQ was well above average, and he had no specific learning disabilities. His mother had had preeclampsia, but the pregnancy and delivery were otherwise normal. There was a family history of hyperactivity and of alcoholism.

When we first saw the child, he did not seem to be hyperactive or excessively distractible. Results of physical and neurologic examination, including an EEG, were normal. His height was 130 cm (75th centile) and his weight was 24 kg (45th centile).

We wanted to get a baseline and suggested to the child's mother that she stop giving him the medication because of the curious symptom pattern and the equivocal nature of his drug response. The drug was stopped after 7 months of treatment.

Two days later, the child began to have severe nausea, vomiting, and abdominal cramps. He could keep no liquids down, and on Tuesday he was admitted to a community hospital, where he was found to be almost 10% dehydrated, acidotic, and ketonuric. A CBC and a WBC count were normal. He did not have a fever, and there were no similar illnesses at that time among his family, neighbors, friends, or peers. He was treated with intravenuous fluids and electrolytes and discharged 2 days later. For 2 weeks after his discharge, he vomited whenever he ate solid foods.

He has done well since that time, and has had no recurrence of gastrointestinal problems. His behavior problems have not returned, and he is currently doing well in a third-grade class with no medications.

Discussion

Of all the tricyclic antidepressants, only imipramine is approved for use in children for the temporary relief of symptoms of nocturnal enuresis (1). However, over the years, imipramine, amitriptyline, other tricyclics, and even the monoamine oxidase inhibitors have been used in children for a variety of problems, ranging from hyperkinesis to petit mal seizures (1). There is no evidence that imipramine, the most commonly used tricyclic among children, is superior to stimulant drugs in the treatment of hyperkinesis (2). There are few studies on the use of amitriptyline in childhood disorders (1). Yepes and associates (3) found that the drug was comparable to methylphenidate among "behaviorally disordered" children in some of its effects but tended to be sedating.

Nausea and vomiting have been described in connection with withdrawal from neuroleptic drugs (4–6). Children appear to be particularly sensitive to the effects of neuroleptic withdrawal, and a syndrome characterized by gastrointestinal symptoms, peculiar movements, agitation, and autonomic disturbances has been described (7).

Withdrawal symptoms, including gastrointestinal complaints, have been described among patients treated with imipramine (8, 9). To our knowledge, however, an amitriptyline withdrawal syndrome similar to the case described above has never been reported, and tricyclic withdrawal symptoms have not been described in the pediatric age group.

It is a common belief among clinicians that the abrupt discontinuation of any strongly anticholinergic drug may provoke withdrawal symptoms. Amitriptyline is the most strongly anticholinergic of all the tricyclics (10), and it seems likely that this child's severe reaction was induced by the abrupt withdrawal of an anticholinergic influence.

Although this case report does not make an ironclad case for the existence of an amitriptyline withdrawal syndrome in children, it does suggest certain cautions. First, amitriptyline should not be used in the

treatment of hyperkinesis when other more familiar drugs are available. Second, children who are treated with amitriptyline probably should not be abruptly withdrawn from the drug.

Chronic Amitriptyline Toxicity

BY EARL L. GILLER, JR., M.D., PH.D., DONALD S. BIALOS, M.D., JOHN P. DOCHERTY, M.D., PETER JATLOW, M.D., AND LAURIE HARKNESS, M.S.W.

Recent work has demonstrated that the therapeutic response of depressed patients to amitriptyline occurs at total tricyclic plasma concentrations within a range of approximately 75-200 ng/ml (1). Severe, acute overdosage, with total tricyclic plasma levels greater than 1000 ng/ml, is generally recognizable by such clinical signs as decreased consciousness, marked anticholinergic manifestations (tachycardia, mydriasis, blurred vision, dry mouth, urinary retention, decreased bowel activity, agitation) (2), and ECG changes (prolonged PR and QRS intervals, diffuse ST-T wave changes), with QRS widening being the best indicator of high drug plasma levels (3).

Chronic excessive levels, however, may be associated with milder toxic symptoms that are difficult to distinguish from depressive symptoms. Plasma nortriptyline levels over 140 ng/ml are associated with poor antidepressant response (4) that may be confused with undermedication. Thus the clinical state of patients with chronic total antidepressant plasma levels between 200 and 1000 ng/ml can help to clarify when toxic effects begin and what those effects are. This report describes a patient with total antidepressant levels of over 700 ng/ml who had received a daily dose of 250 mg of amitriptyline for 3 years and who, in retrospect, appears to have shown specific symptoms of toxicity.

Case Report

Mr. A., a 54-year-old married man, had been hospitalized six times since 1943 for depressive episodes and suicide attempts. He became alcoholic in 1955, and a liver biopsy in 1962 showed Lannec's cirrhosis. In 1973 he was hospitalized for depression and treated with 150 mg/day of amitriptyline for 4 months. He then took an overdose and was thought to have a subendocardial infarction with enzyme and ECG changes (QRS widening, diffuse ST and T abnormalities). Subsequent ECGs were normal. After discharge, he was restarted on amitriptyline, which was increased to 250 mg/day in 1975 for continued feelings of depression, anergia, and anxiety. This dose was continued until he began to participate in an antidepressant withdrawal study in June 1978. On baseline evaluation he was found to be mildly confused, agitated, and nervous. Anticholinergic symptoms of dry mouth, blurred vision, constipation, and urinary hesitancy were mild to moderate. One week later, after his daily dose had been tapered to 175 mg, he was more coherent and less nervous but coincidentally was hospitalized and treated surgically for a perforated duodenal ulcer. Amitriptyline was stopped on hospitalization. An ECG showed QRS and PR interval increases and diffuse ST and T changes. Steady-state baseline plasma antidepressant levels drawn 1 and 2 weeks earlier and assayed (5) at this time showed total levels of 744 ng/ml (amitriptyline=492, nortriptyline=252) and 720 ng/ml (amitriptyline=443, nortriptyline=277). At discharge, he was not confused and was more relaxed, communicative, and cheerful than he had been in years. When questioned at discharge, Mr. A denied excessive drug ingestion. He subsequently became depressed and was again started on 50 mg of amitriptyline, which he independently increased to 150

mg/day. After 1 month, plasma levels at this dose were 294 ng/ml of amitriptyline and 91 ng/ml of nortriptyline. His dose was reduced.

Discussion

This patient had chronically toxic plasma levels of amitriptyline and nortriptyline, possibly as a result of impaired liver metabolism of the drug secondary to his cirrhosis. The almost identical drug concentrations obtained 1 week apart and the very high nortriptyline levels are more compatible with steady-state excessive levels than acute overdose (6). Equivalently high levels were seen after the patient was given a lower daily dose. The assessment of his myocardial infarction in 1973 was, in retrospect, complicated by amitriptyline treatment, since the ECG changes were similar to those seen with high antidepressant plasma levels. Similar ECG changes were seen in 1978 when Mr. A had greatly elevated antidepressant plasma levels. His mild confusion and agitation are consistent with the more severe symptoms of agitation, restlessness, and even delirium seen with higher plasma levels (1).

When tricyclic antidepressants were introduced into clinical use, insufficient dosage was the most common cause of poor medication response. Clinicians learned to increase the upper limit for daily dosages from 150 mg to 300 mg. This case illustrates the problem that, as in neuroleptic treatment (7), symptoms resulting from excessive drug blood levels may be interpreted as reflecting insufficient levels. This dose is then increased instead of decreased, which causes further toxicity. Thus patients taking tricyclic antidepressants who have impaired drug clearance, including geriatric patients (8) and alcoholics, and who show signs of confusion, agitation, or nervousness, even without prominent anticholinergic symptoms, should have plasma drug level determinations. If this is not possible, a trial of dosage reduction should be considered.

Trihexyphenidyl Abuse for Euphorigenic Effect

BY DANIEL A. GOGGIN, M.D., AND GEORGE F. SOLOMON, M.D.

Synthetic anticholinergics are used to treat Parkinson's disease and extrapyramidal side effects of psychotropic medication. The clinical and pharmacologic literature contains references to various responses to anticholinergic CNS stimulation, particularly toxic psychosis. However, there is little information about the affective aspects of CNS responses to anticholinergics. We will describe the case of a patient who abused trihexyphenidyl for a prolonged period to obtain a euphorigenic effect.

Case Report

Mr. A, a 40-year-old chemist with administrative and scientific duties, was seen initially with the chief complaint, "I think I'm going to pieces." He had become seriously depressed as a result of his suspicions, which had been intensifying for 2 years, that his wife was having an affair. He stated that his wife had done nothing to validate his fears. Five days after she left for a vacation with relatives the obsessive thoughts had become so anxiety-provoking that Mr. A had not eaten or slept, and he sought treatment. He reported a weight loss of 4.6–5.4 kg in the past year, decreased interest in routine activities, intermittent and terminal sleep problems, and recent onset of feelings of futility about life. He had no known allergies or history of drug abuse.

The authors thank Ronald M. Imoto, Pharm.D., Patrick D. Ginn, Pharm.D., Richard E. Land, D.O., Lyn I. Hunt, M.D., and Owen K. Tsuchiya, M.D., for consultation and editorial assistance.

The initial diagnosis was depressive neurosis of moderate severity with psychotic trends and obsessive character. He was started on thiothixene, 5 mg t.i.d., and began long-term psychotherapy. The choice of thiothixene was based on clinical reports of its efficacy in treating depression associated with anxiety, agitation, and obsessive features (1–3). Two days later he was given trihexyphenidyl (Artane), 2 mg t.i.d., to treat symptoms of akathisia. The trihexyphenidyl dosage was increased to 4 mg. t.i.d. 2 weeks later for recurring akathisia, which resolved within 72 hours. After 2 months, his anxiety and ruminations had decreased and his sleep pattern had improved, so his dosages were reduced to 5 mg b.i.d. of both thiothixene and trihexyphenidyl. After he had been stabilized in treatment for 4 months, he was given a prescription for a 1-month supply with two refills of both medications. He became more despondent in the ensuing month but withheld this information and treated himself, first with increased doses of thiothixene and then with 35–40 mg of trihexyphenidyl daily. He told the therapist what he was doing after he depleted his prescription. He felt that the trihexyphenidyl had a definite antidepressant effect that thiothixene lacked. He denied adverse side effects or other drug abuse during that period. Hospitalization was considered, but Mr. A responded to doxepin, up to 250 mg/day, and to intensive therapy.

His depressive symptoms diminished during the next 3 months, and the doxepin dosage was gradually reduced to 100 mg/day. However, shortly after this period he synthesized trihexyphenidyl and ingested approximately 25 mg of the chemically impure compound over a 6-hour period. He experienced acute tachycardia, nausea, weakness, restlessness, and faintness, which led to a brief hospitalization (72 hours). He denied other drug abuse. He stated that he wanted the trihexyphenidyl because "I was just tired of looking at people who appeared to not be depressed, and I wanted to feel good that way again." Subsequently, doxepin was stopped and amitriptyline, 75 mg h.s., was started. After several sessions Mr. A stopped therapy, but he continued to take amitriptyline for 6 months. When he was seen in follow-up a month later, he felt recovered from his depression and denied further abuse of trihexyphenidyl "because of the possible consequences to my health and job."

In one session, Mr. A described his subjective feelings during his first instance of trihexyphenidyl abuse as follows: "I really felt so bad, I felt nothing was worthwhile. Everything was very bad, dark, I wanted to crawl in a hole. I took two Navane [5 mg] capsules. They didn't do anything for me; I just kept sinking. Then I took two Artane [5 mg]. That brought me up to feel okay or normal. After the response I could think about my problem, know I had it, but I didn't feel depressed about it. But I was extremely depressed before I took them [Artane] . . . sick."

Mood-Altering Effects of Other Anticholinergics

It has been our experience that jail inmates hoard and trade trihexyphenidyl, which they use to get high, but do not generally abuse benztropine. However, a colleague related two cases of benztropine abuse for mood-altering effect, in one case to relieve anxiety and in the other to obtain a high (S. Castro, M.D., personal communication). Jellinek (4) reported on eight individuals who rejected discontinuation of trihexyphenidyl and biperiden, prescribed for dyskinetic side effects of phenothiazines, because they "did not feel as well" without the drugs, which had an energizing, mood-elevating effect. Another colleague recently noted that five of his patients had taken 3–4 times the prescribed dosage of biperiden to obtain a euphorigenic effect (W. Bernstein, M.D., personal communication). Fink and associates suggested in one study that a chlorpromazine-procyclidine regimen might more effectively treat depression than chlorpromazine alone (5).

Discussion

MacVicar (6) and Rubinstein (7, 8) have emphasized the abuse potential of anticholinergics, particularly by patients with histories of multiple drug abuse, and have cautioned against excessive or lax prescription of these drugs. The use of an anticholinergic specifically to relieve a depressed mood is minimally documented. Bolin (9) reported that a 32-year-old woman was treated for spastic torticollis with trihexyphenidyl, which induced a sense of well-being that counteracted depressive feelings. She took higher doses (eventually reaching 24–30 mg/day) as life stresses accumulated, and developed a toxic psychosis.

In the case we have described the patient clearly abused trihexyphenidyl to alleviate his depressed state and to "feel good" again. He discriminated between his responses to trihexyphenidyl and to thiothixene. His sustained use of trihexyphenidyl without intolerable side effects, in daily doses that usually result in toxic psychosis, implies individual differences in CNS response to anticholinergics and indicates the need for further research on the role of cholinergic pathways in affective states.

Sleep Architecture in Psychotropic-Induced Somnambulism

SIR: In "Filicide During Psychotropic-Induced Somnambulism: A Case Report" (November 1978 issue) Daniel J. Luchins, M.D., and colleagues stated that they were unaware of reports documenting frequent movement and awakening from stage 4 sleep in patients with somnambulism or the onset of somnambulism after at least one REM period.

In fact, there have been papers which address both of these issues. Broughton (1), in his classic paper on somnambulism, night terrors, and enuresis as disorders of arousal, cited four references which demonstrated that sleepwalkers exhibit many movements during stage 4 sleep independent of the somnambulism itself. Additionally, Fisher and associates (2) reported that patients with night terrors (also a stage 4 phenomenon) experienced significantly more awakenings from stages 3 and 4 sleep than a control group. Indeed, Broughton hypothesized that it is a constellation of physiological factors, of which increased awakening from stage 4 sleep is a part, that predisposes a patient to a particular disorder of arousal such as somnambulism or night terrors.

Several authors have also noted that it is not uncommon for episodes of somnambulism and night terrors to occur after the first REM period (2–4). The finding in thioridazine-induced somnambulism that the episodes occurred after at least one REM period had elapsed may be related to that drug's ability to increase stage 4 sleep. This increase probably occurs after the first REM period when drug plasma levels begin to rise following the evening dose. One could postulate that in patients who experience neuroleptic-induced somnambulism the drugs induce a physiological state during stage 4 sleep similar to that in patients who have endogenous somnambulism. Therefore, it would be of interest to know if their patient's sleep architecture, especially in regard to movement and awakenings from stage 4 sleep, was different on the nights she walked in her sleep from the nights when she did not.

DENNIS S. CHARNEY, M.D.
New Haven, Conn.

Dr. Luchins and Associates Reply

SIR: We found interesting Dr. Charney's suggestion that thioridazine might induce a physiological state in stage 4 sleep (increased movements and awakening) similar to what is found in "endogenous" somnambulism. However, we do not believe it applies to our patient. She showed frequent movement and awakening from stage 4 sleep when she was both on and off medication. In fact, there were nights when she was not taking medication and would sit up in bed during stage 4 sleep. On nights when she was taking medication and did not sleepwalk, there was no increase in movements or awakening as compared to nights without medication. It seems to us that the thioridazine (particularly in combination with chloral hydrate) "disinhibited" a mechanism that normally suppressed full-blown somnambulism in a predisposed individual.

Family Planning for the Mentally Ill

SIR: The excellent article by Ming T. Tsuang, M.D., Ph.D., "Genetic Counseling for Psychiatric Patients and Their Families" (December 1978 issue), makes it appropriate to reiterate the urgent need of mentally ill patients and their spouses for family planning services and that this is a responsibility of the psychiatric profession.

The birth rate among mentally ill women has risen substantially within the past two decades. By virtue of their social and psychological problems, these women have difficulty obtaining and utilizing family planning services. This fact, coupled with growing use of community and child-care services, coincides with a more general concern for popu-

lation control and family planning programs. Because pregnancy, child-birth, and child-care may contribute to recurrences of psychotic or depressive episodes, and because the children of mental patients are often unwanted and tend to be disadvantaged psychologically, socially, and educationally, this sector of the population needs adequate family planning services.

Both the need and desire for such services have been documented by the patients themselves. Lack of knowledge about and access to services, fear and ignorance about methods, and poor communication with sexual partners and therapists prevent these women from getting the care they need and want. When asked if they would like such services offered in conjunction with hospital care, the hospitalized psychiatric patients we surveyed unanimously answered yes (1). The prevalence of unplanned and unwanted pregnancies and the concomitant emotional distress further document this need (2). If the pregnancy is carried to term, the unwanted child is often blamed for his or her mother's distress and is consequently deprived of maternal care and attention. Since the child may become a ward of the state or be adopted, he is likely to incorporate the blame and perceive himself as worthless. In addition, the associated experiential and potential genetic deficits may, as Dr. Tsuang has documented, decrease the child's potential for normal development.

There are three major arguments favoring the integration of family planning services with other mental health services. First, the mental patient's welfare requires an amount of time and special attention that standard community family planning programs cannot provide in order to overcome the psychological and informational barriers to effective contraception. Second, the potential handicaps of an unwanted pregnancy—which would affect the child as well as his family—make it ethically necessary to inform these women about family planning and allow them to opt for an alternative. Third, this type of planning is an integral part of primary prevention in mental illness and thus belongs in every mental health care setting throughout the country. Deinstitutionalization and community maintenance make it imperative to provide screening, counseling, follow-up, and any additional services to ensure adequate education and use of contraceptives for mentally ill women.

Over the past five years, in collaboration with both the national and local Offices of Family Planning, Department of Health, Education, and Welfare, we have developed family planning services in three state mental hospitals and one community general hospital that has a psychiatric ward and have provided consultation to two private hospitals with psychiatric wards as well as to a community mental health guidance center. The patients and staff welcomed these services, which were delivered in a variety of psychiatric settings. Follow-up studies have demonstrated that a significant proportion of these patients continued using contraceptives after leaving the hospital.

I have attempted to point out the need of psychiatric patients not only for genetic counseling but for family planning services as well. Based on our experience, these services can be effectively delivered in the psychiatric hospital. We wish to express our willingness to consult with any psychiatric hospital in the nation that may wish to provide these services as part of every woman's right to good medical care.

Imipramine and Delusional Depressions

SIR: In "Imipramine Response in Deluded Depressive Patients" (July 1978 issue) Frederic Quitkin, M.D., and associates reported that delusional depressed patients respond to imipramine as well as depressed patients without delusions, which contradicts our observation that delusional depressed patients do not respond to imipramine (1). We feel there are major differences in the way the data were collected and in the populations studied that preclude any meaningful comparisons between these two studies.

Dr. Quitkin and associates' retrospective analysis used scale scores from the LORR multidimensional features, and the authors noted that psychotic features were generally "slight to mild" and that "delusions and hallucinations were not prominent features of the symptoms." In our study, a clinical evaluation was used to determine whether the patient was delusional, and patients about whom there was uncertainty were excluded. In marked contrast to the Quitkin and associates study, our patients' delusions were of primary importance and were often their chief complaint.

Dr. Quitkin and associates stated that we did not present the criteria we used to define a delusional depression. In fact, that definition was included in our original report and elaborated in a subsequent paper that dealt with the history of the delusional concept in depression (2). It has been our impression that profound feelings of guilt, worthlessness, and pessimism are common in severe depressions and that even when held with a quasi-delusional conviction they do not constitute delusional ideation. We considered a patient who felt his life had been wasted (with abundant evidence to the contrary) as nondelusional. However, a patient who thought he had committed a crime and was convinced he should be punished was considered delusional, as was a woman who was convinced the FBI wanted to deport her because she was not worthy of citizenship. We are perplexed as to how one defines a "slight to mild" delusion. Certainly our population was not mildly delusional.

There are other significant differences between the two patient groups. In the 60 patients we studied (3), 28% were delusional by our criteria; Dr. Quitkin and associates found 75% of their 36 patients delusional. The mean age of their patients was 38, whereas the mean age of our 13 delusional patients was 61 years. Before participating in the study, their patients "had failed to respond to nonsomatic hospital treatments," presumably a prolonged period of hospitalization. In contrast, our delusional patients were so sick that an active drug trial of more than 4 weeks could not be justified. Thus, our patients would seem to have been more severely ill, older, and, most importantly, more clearly delusional than theirs. These are large and, we think, clinically significant differences. Dr. Quitkin and associates suggested that delusional patients may have required higher doses. Of our 13 patients, the 2 who responded had plasma levels of 50 and 100 ng/ml, respectively, and the 11 nonresponders had a mean level of 208 ng/ml, with a range of 65–535 ng/ml. Among nondelusional patients we have found approximately

200 ng/ml to be a therapeutic antidepressant plasma level. Thus we do not feel that nonresponsiveness among the delusional depressives was related to an inadequate concentration of drugs.

We think that because of major differences in the patient population studied, the ways in which data were collected, and the criteria used for defining delusional patients, the results obtained by Dr. Quitkin and associates cannot be compared with our data. However, it is also important to note that both of these studies are retrospective observations and involve only imipramine. As a result they are limited, and both suffer the pitfalls so common to retrospective observation. We continue to think that delusional patients do poorly on imipramine and very well with ECT. We do not know that other treatments do not work—we simply have no information. Delusional depressions are a regular part of clinical practice, and we heartily agree with Dr. Quitkin and associates that this issue deserves a careful prospective evaluation.

Dr. Quitkin and Associates Reply

SIR: It may very well be that our results are different from those of Dr. Glassman and associates because of different characteristics of our samples. However, there remains the possibility that if they had used a higher dose their results would have resembled ours. The question is, which is the better predictor of therapeutic effect—blood level or daily dose? One would, of course, like more data, but an appraisal of the present literature, which includes two double-blind prospective controlled studies showing that 300 mg/day was superior to 150 mg/day (1, 2), leads us to believe that a trial of imipramine should not be considered adequate unless a dosage of 300 mg/day has been reached, and we believe such a dose should be tried unless adverse reactions supravene.

In the study by Glassman and associates (3) a fixed dose of 3.5 mg/kg per day was used, which, given the usual weight of women, would result in a dose of approximately 200 mg/day.

We all agree that this important question should be resolved by future research. We have, in the course of a study of desipramine, 300 mg/day, in depression, treated four patients with prominent delusions who met the criteria of psychotic depression of the Research Diagnostic Criteria (4). Three had a marked clinical improvement with remissions of both delusions and depression; the fourth refused to continue in the study.

This anecdotal experience adds to our conviction that it is premature to conclude that psychotic depressives should be treated with ECT without a trial of tricyclic antidepressants first.

Successful Treatment of Hypertension—Compliance or Marital Therapy?

SIR: The title of the paper by Frank Summers, Ph.D., "Severe Hypertension Treated Successfully by Marital Psychotherapy" (August 1978 issue) was provocative but misleading. The patient described in the paper was treated not only by marital psychotherapy but by large doses of five effective antihypertensive drugs. Although psychological factors probably play a role in the etiology of hypertension (1), I doubt that the decreased stress and tension perceived by the patient caused the blood-pressure-lowering effect of psychotherapy. A much more likely explanation is that the patient did not respond initially to medication because she did not take it as prescribed. Then psychotherapy decreased blood pressure by improving the patient's compliance.

Inadequate compliance of patients with the therapeutic regimen is the most important factor in hypertension treatment (2). The compliance decreases as the number of pills prescribed increases, and it is very doubtful that the patient was taking all of her 17 daily pills. Dr. Summers describes the patient as deeply depressed, and this could also contribute to low compliance. Even without suicidal tendencies, a depressed patient is hardly concerned about his or her physical well-being and therefore is not motivated to take medication. Finally, large doses of antihypertensive medications usually cause some side effects. The lack of these in this case also indicates poor compliance.

Compliance of hypertensive patients is not affected by increased knowledge about the disease, but it is improved by a behaviorally oriented approach (3). Summers' paper suggests that psychotherapy might be an effective strategy to improve blood pressure control in a noncomplying patient.

Dr. Summers Replies

SIR: I disagree with Dr. Volicer's contention that my paper was misleading. The fact that he did not cite any misleading statements in my paper supports this objection. The body of his letter attempted to defend his speculation that my patient was helped by a change in her medication compliance habits rather than a reduction in tension brought about by psychotherapy. This implies that I had proposed the latter as her route to improvement. Of course I made no such statement. The limitations imposed by the Clinical and Research Reports section left me no space to speculate about the vehicle of my patient's rather dramatic change. I reported the facts as I saw them, and the fact is that the reduction in her blood pressure began after a particularly poignant marital therapy session. Had I not reported this sequence, I would have been guilty of misleading my readers.

I do agree that Dr. Volicer's speculation regarding the means by which psychotherapy helped effect a lowering of the patient's blood pressure is plausible. But I also entertain the hypothesis of decreased stress, especially since the patient's relief was quite apparent. However, I simply do not have the data to make a definitive judgment. The patient did not discuss medication compliance during our sessions, nor did she talk about it with her physician. Dr. Volicer's certainty about the implications of my paper seems unwarranted. Had I had the space, I would have presented alternative speculations of possible reasons for the effects of psychotherapy on the patient's reduced blood pressure; any statement in this regard is speculation.

Chicago, Ill.

More on Trimipramine and Alcohol

SIR: The issue of possible idiosyncratic response to trimipramine in middle-aged men suffering from intermittent bipolar affective disorder compounded by dipsomania was discussed in my letter, "Trimipramine and Relapses of Symptomatic Drinking," and Dr. Akiskal's reply in the October 1978 issue of the *Journal*.

Trimipramine enjoys an exceptional position among the tricyclic antidepressants, having an anxiolytic effect second only to chlorprothixene (1) and failing to suppress REM sleep (2), as most compounds of the group do. Moreover, it is the only tricyclic antidepressant not explicitly contraindicated in combination with MAO inhibitors (3).

These oddities of trimipramine could perhaps explain in some way the fact that one of the patients I described in my previous letter was able to stabilize emotionally and reduce considerably his habitual ingestion of alcohol on 150 mg/day of amitriptyline, whereas trimipramine seems to have led to exceptionally heavy drinking that culminated in a predelirious condition.

Another alcoholic patient, aged 35, who was seemingly dependent on thioridazine, diazepam, and methyprylon and had a long history of impulsive behavior and pronounced mood swings, developed a typical picture of delirium tremens within a few days of introduction of trimipramine, 100 mg h.s.

A 52-year-old salesman who had recently separated from his wife was diagnosed as suffering from a depressive reaction against a background of cyclothymic personality. He failed to improve with various combinations of antidepressants, minor tranquilizers, and hypnotics for several months. He was then given trimipramine, 50 mg t.i.d., which led to his being practically recovered within about 2 months. About 6 months later he required urgent attention for the first time in his life for a bout of heavy drinking of over 2 weeks' duration that was accompanied by reckless spending and extensive traveling, a definite flight of ideas, and suicidal impulses. He had been taking 200 mg/day of trimipramine for about 6 weeks upon the prescription of another physician for a well-documented depressive relapse.

All these cases would favor the possibility of trimipramine triggering a switch to hypomania; this is warned against by the manufacturer (4) as manifested chiefly by an excessive use of ethanol.

This does not seem to be a problem unless there is a background of intermittent bipolar affective disorder. I have followed during three consecutive episodes of agitated depression, compounded by heavy drinking and occurring apparently around the anniversary of her husband's death, a 62-year-old woman who had become helpless and lonely after she was widowed. Each time she recovered entirely within a fortnight of the introduction of trimipramine at the dose of 75–100 mg h.s. She had no history of periodic swings of mood and activity. Is the difference in gender related to the opposite, beneficial response to trimipramine in regard to excessive drinking in this case?

Another patient's case seems to militate against such a conclusion. An anxious 57-year-old man with a 25-year history of alcohol abuse who was prone to depressive spells had been abstinent for 6 years. He was seen in a state of agitated depression and was given clomipramine, 100 mg/day and then amitriptyline, 50–150 mg, with no improvement. Within 10 days he improved on 200 mg/day of trimipramine and remained well for the next 5 months of follow-up care, with maintenance doses of approximately 75–100 mg/day. He has never returned to drinking.

Although the number of these clinical observations is insufficient to establish as a well-founded fact this particular untoward response to trimipramine in a subgroup of bipolar affective patients, the subject seems to merit further investigation. Discounting the above incidents as merely returns to pretreatment (drinking) behavior would not do justice to the issue.

More on Bioequivalence of Tricyclics

SIR: The case report by Robert B. Ostroff, M.D., and John P. Docherty, M.D., on "Tricyclics, Bioequivalence, and Clinical Response" (December 1978 issue) prompts me to

share recent experiences in which four outpatients had substitutions of tricyclic antidepressant by the hospital pharmacy.

The patients, two men and two women ages 38–54, had been taking one brand of amitriptyline in dosages ranging from 100 to 450 mg/day over 6 months for depression. Each patient participates in supportive psychotherapy and is seen for one hour every two to four weeks; there have been no recent changes in scheduling. All four patients had experienced an excellent clinical response, with improved sleep pattern, appetite, energy, pleasure, and sense of well-being.

I routinely prescribe no more than a 4-week supply of medication, and all of these patients happened to obtain refills during a 3-week period after the hospital pharmacy began to substitute another brand of amitriptyline. (Illinois law allows pharmacists to substitute generic drugs or other name brands unless the physician indicates "no substitution" on the prescription.) Each patient called me approximately 10 days after the substitution and complained of feeling worse, particularly in terms of decreased energy and disturbed sleeping patterns. Interestingly, three patients noted that the pharmacist had discussed the substitution and reassured them; they wondered aloud, "Is my mind playing a trick on me with the new colored pill, although I definitely do feel worse?" I initially reassured the patients regarding the substitution, but their discomfort persisted and I offered them new prescriptions for the original brand, marked "no substitutions." I have started to do this with other patients for whom I prescribe tricyclic antidepressants. This experience led me to wonder if there were bioequivalence differences among the tricyclic antidepressants, as is the case with digitalis.

Dr. Ostroff's report and a recent letter by Ayd (1) add confirming emphasis to the possibility of important bioequivalence differences. Physicians prescribing antidepressant tricyclics should indicate a brand name with which they are experienced and mark "no substitutions" on the prescription until this problem is better researched.

Double Standards or Different Standards?

SIR: In his letter, "Editorial Double Standards?" (December 1978 issue), Michael A. Taylor, M.D. unfairly attacked *Journal* editors for using what he described as a double standard in accepting manuscripts. I do not believe he has proven a double standard at all, and I wish the Editor had not accepted culpability so quickly.

Dr. Taylor's implicit premise is that journals should accept only one type of manuscript, which I shall label statistic-based. This is the type Dr. Taylor prefers. Writers of this sort of article should maintain a certain standard by using control groups and unbiased raters. Dr. Taylor complains that his articles must live up to this standard, while Dr. Arieti's do not.

Why must a journal editor subscribe to Dr. Taylor's notion that all manuscripts be of the statistic-based type? An editor may believe there is a place for articles of a purely descriptive, theoretical, or even a musing-humorous nature. If the editor sets a high, but different, standard for each type of article, would Dr. Taylor deny him this prerogative?

If an editor does what I have just described, could one say (as Dr. Taylor does) that the editor has a double (or triple, or quadruple) standard—or that he has two to four categories of manuscripts he accepts, with a single high standard of excellence for each? The latter seems a more accurate statement.

In setting the standard for descriptive articles, criteria worth considering are the number of patients the observer has worked with intensively over a period of time (i.e., his experience); the perceptiveness of his observations (best demonstrated by his prior writings or lectures); and his skills at exposition.

I do not wish to imply that description is nonscientific. The scientific method begins with observation, and in psychiatry this means a careful, accurate observation of clinical phenomena in patients one knows rather well. (Observing the patient and being certain of one's interpretations are vastly underrated abilities, achieved only by a skilled clinician.) Such work generates many of the basic data that are later correlated, chi-squared, and generally chewed on by statistic-minded psychiatrists. This is not intended pejoratively, because I recognize their work as comprising a distinct part of the total scientific enquiry.

But the scientific method does not begin with collected data; it begins with a first-hand accurate observation of reality. Hypotheses may then be formed. Once formulated, they will eventually be subjected to verification by skilled clinicians like Dr. Arieti, who apply the hypotheses to patients they have worked with firsthand. Interpreting the results accurately depends upon correct observations and correct controls and analysis.

There are several types of scientific enquiry, each involving different phases, and I think a psychiatric journal should encompass them all. I do not see any double standard, merely single standards applied to several categories of manuscripts.

Greenwich, Conn.

A Quotation Problem

SIR: In the article "Adult Minimal Brain Dysfunction and Schizophrenia: A Case Report" (December 1978 issue), Leighton Y. Huey, M.D., and associates quoted our work (1) incorrectly. We did not say that imipramine is helpful in schizophrenics characterized by "soft neurologic signs." In fact, the subgroup of schizophrenics who are most prone to soft neurologic signs are those who have very poor premorbid sociality and are not only poor responders to antipsychotics but are most likely to do poorly when given tricyclic antidepressants, i.e., to develop an exacerbation of their psychotic symptoms (2, 3).

Propranolol in Breast Milk

SIR: In his article "Side Effects in the Neonate from Psychotropic Agents Excreted Through Breast-Feeding" (July 1978 issue), Jambur Ananth, M.D., M.B.B.S., D.P.M., stated that one paper (1) indicated propranolol is excreted freely in breast milk and the actual plasma-to-milk ratio is greater than 1:1.

I believe Dr. Ananth's interpretation of the propranolol data is incorrect. Two papers have reported propranolol levels in human milk (1, 2). The maximum milk level reported was about 120 ng/ml three hours after a maternal dose of 160 mg p.o. (1). The second paper contained a laboratory reporting error, which when corrected (3) indicated a maximum milk level of 30 ng/ml two hours after a maternal dose of 40 mg p.o. The two papers are therefore in agreement. The second paper measured sequential plasma and milk levels in one patient. Maximum milk levels were only about half of peak plasma levels. If milk levels do exceed plasma levels, it is unlikely that they exceed them by very much or for longer than a brief period (4).

One can estimate an infant's theoretic maximum drug intake by assuming that an infant takes in 165 ml/kg of milk per day (4). If the infant nurses at the time of peak propranolol levels (which is unlikely) and the mother is taking the rather high dose of 160 mg, the infant would receive only 20 μg/kg per day. This is about three orders of magnitude less than the reported therapeutic dose in infants of 14.4 mg/kg per day (2).

There appears to be no basis for Dr. Ananth's dogmatic statement that "under no circumstances should this drug be administered to a nursing mother, and no mother taking this medication should be permitted to breast-feed her infant."

Dysorexia and Self-Mutilation

SIR: Several of us who have studied varieties of self-mutilating behavior (1–5) have noted an incidence of dysorexia—bulimia, binge-eating, and vomiting—and periods of anorexia in such patients; the figures were over 62% in the series done by Rosenthal and associates (4) and 75% in my study (2). Japanese researchers investigating binge-eating and dysorexia have described the significant occurrence of self-mutilation. However, the majority of the Western literature on anorexia nervosa fails to mention such behavior, and researchers in this area do not seem to look for, inquire about, or record such mutilations. In none of the self-mutilating anorexic patients I have seen have the mutilations been recorded in the official case summaries, and they seem often to be omitted from the medical records altogether.

There are some interesting similarities between self-mutilating and anorexic patients, and an association, if one exists, could suggest further useful means of exploring both conditions. Anorexic and self-mutilating patients share characteristics such as an altered body image and self-control problems, difficulty in expressing or responding to emotions verbally rather than physically (by not eating or by cutting), difficulties in accepting adult sexual roles, and themes of loss and separation and reactions to loss.

I would be interested to know whether others have noticed this tentative relationship.

Heat and Neuroleptics: A Deadly Combination

SIR: I would like to congratulate Stephan C. Mann, M.D., and William P. Boger, M.D., on their timely and much needed article, "Psychotropic Drugs, Summer Heat and Humidity, and Hyperpyrexia: a Danger Restated" (September 1978 issue), and add the following case report to the literature. This tragic case involved a robust young man who had been stabilized on the same medications for many months and whose DIC (disseminated intravascular coagulation) syndrome proved fatal.

Mr. A, a healthy 25-year-old single man, had been in psychiatric treatment for a number of years following a lengthy inpatient hospitalization. In spite of a diagnosis of chronic paranoid schizophrenia, he managed to graduate from a prestigious college, obtain gainful employment, and live in a cooperative boarding house. For 4 months he had been maintained without side effects and with good results on 64 mg of perphenazine, 150 mg of imipramine, and 10 mg of trihexyphenidyl HCl. The latter had been instituted because of persistent signs and symptoms of akathisia. Attempts to decrease the medication led to sleeplessness, agitation, and depression.

In August 1975, during a severe summer heat wave, coincidentally while his therapist was on vacation, the patient became progressively confused and agitated. Earlier in the day he had walked through the streets of his home town

distributing political leaflets. Unable to contact the therapist's substitute, Mr. A wandered into the unventilated, windowless washroom of his rooming house. Six to eight hours later he was discovered dying in the washroom, where the temperature was about 105°F (40°C).

Rushed to the emergency room of the local hospital, Mr. A remained unresponsive, with fixed, dilated, and unresponsive pupils. His skin was hot and dry. Temperature was 111.2°F (44°C) rectally, pulse 150, respiration 15, blood pressure 60/0. Shortly thereafter he became apneic and was intubated. His extremities were flaccid, reflexes were absent, and there were no spontaneous movements. Complete laboratory studies of blood, urine, and spinal fluid were within normal limits. Coagulation studies were also normal.

Mr. A never regained consciousness in spite of emergency treatment with an ice bath and later a cooling blanket, steroids, multiple pressor agents, plasma expanders, and antibiotics. Finally, he developed DIC syndrome with acute gastrointestinal bleeding, as well as a metabolic acidosis and focal seizures. In spite of the addition of fresh frozen plasma, packed red blood cells, cryoprecipitate, and albumin to the regimen, Mr. A died about 3 hours after admission.

Postmortem findings confirmed the diagnosis of heat stroke and specifically revealed diffuse hemorrhagic processes involving the upper respiratory tract, upper gastrointestinal tract and bladder, acute peritonitis and mesenteric lymphadenitis, splenic hemorrhage, hepatic necrosis, cerebral edema, and hemorrhagic pleural and peritoneal effusions. Toxicologic examination of multiple body fluids and tissue specimens was negative.

All physicians, particularly psychiatrists, should warn patients and their families, especially those on combinations of neuroleptics, of the dangers of summer heat and physical exertion. They can urge patients to take less drug, limit exercise, drink adequate fluids, and remain in an air-conditioned room during heat waves. Such a warning might have prevented this patient's tragic demise.

I, too, have been impressed both with the drug manufacturers' reluctance to publicize this serious complication and a general unawareness of this problem among psychiatrists and mental health workers.

RICHARD A. COOPER, M.D.
New Haven, Conn.

SSI, the Sick Role, and Economics

SIR: In "Supplemental Security Income and the Sick Role" (October 1978 issue), H. Richard Lamb, M.D., and Alexander Rogawski, M.D., grapple with important but neglected issues. I agree that SSI as now provided tends to lock people into a disabled role. The recipient suffers but accepts this in return for secondary gain and a feeling of security. The authors' recommended solutions would be an improvement. However, there is an omission of the factor of world economic conditions.

There may not be enough U.S. jobs to go around. Perhaps we are obliged to consider with such patients the alternative of accepting the fate of the position in which they find themselves and focus their energies upon nonreimbursed leisure and good works.

JAMES N. HOOD, PH.D., M.D.
Los Angeles, Calif.

Drs. Lamb and Rogawski Reply

SIR: Dr. Hood correctly points out that it is difficult to obtain income-producing opportunities for handicapped people in an economy which cannot offer full employment for able-minded and able-bodied people. Although this is a problem that must be addressed, it must also be recognized that the relevant social and economic problems are outside the competence and influence of mental health professionals.

Dr. Hood seems to agree with us that more than economic considerations are involved when a person becomes a recipient of SSI. We owe our patients constant attention to questions such as How much "help" is required to compensate for disabilities? When does "help" itself become an injurious influence?

In our article we hope to arouse interest in the possible damaging effects of SSI and we make suggestions for reducing untoward consequences.

H. RICHARD LAMB, M.D.
ALEXANDER S. ROGAWSKI, M.D.
Los Angeles, Calif.

Eye Size Discrepancy in Schizophrenia

SIR: In the past years, I have observed and documented a new physical symptom of schizophrenia, which, to my knowledge, has not yet been described. This ocular symptom consists of discrepancy in eye size, i.e., one eye looks larger than the other ("psychic unilateral exophthalmos", or PUE).

The study was conducted during 1977–1978 at Northville Regional Psychiatric Hospital (NRPH), Northville, Mich. The sample consisted of 336 schizophrenic patients, 16 of whom were diagnosed on admission as having acute schizophrenic episodes and had not taken any psychotropic medication. The diagnostic criteria for schizophrenia included formal thought disorder, delusions and/or hallucinations, flatness of affect, absence of gross medical pathology, and no history of medical conditions that might cause psychiatric symptoms. I selected consecutive admissions for the pathological sample. I then matched the randomly chosen control group of 336 normal individuals with the schizophrenic sample for race, age, and sex.

The technique of detecting difference in eye size was purely subjective and clinical, i.e., no measurements were done. However, I relied on three independent observers to contest or support my subjective impressions about the discrepancy in eye size. These observers were not told the subject of my study; they were asked only to look at the face of the subject and make a written report concerning any peculiar finding. They also did not know to which sample the subject belonged. Interrater reliability was found to be 90%.[1]

Of the 336 schizophrenics in this study, 159 (47.3%) showed clear evidence of discrepancy in eye size. Ninety-five patients in this group had a right eye larger than the left one, and the opposite was true for the 64 other patients. The magnitude of the ocular symptom was described as marked in only 4 cases, as moderate in 130 cases, and as mild in 23 cases. The eye that looks markedly or moderately larger actually protrudes from the orbital cavity. This finding justifies

[1]The data were analyzed by John B. Moir, Director of Psychology at NRPH, and Barbara Robertson.

the use of the term PUE. In 16 of the 23 cases in which the symptom was considered mild, the clinical impression was that there seemed to be a reduction of the palpebral fissure.

Ten of the 336 normal people in the control group showed the same type of ocular symptom observed in the schizophrenic sample in moderate or mild degree. In 7 of 10 cases, the impression was of a reduced palpebral fissure.

The 47.3% incidence of discrepant eye size in the schizophrenic patients compared to the 2.9% incidence in the control group (chi-square significant at .001 level) indicates that the ocular symptom and schizophrenia correlate statistically at a very high level of confidence. Such a correlation was not found between the ocular symptom and several other variables such as race, age, sex, dominance of the left hemisphere of the brain, severity of psychopathology, and medication administered.

The data reported in this study indicate it may be possible to predict the presence of schizophrenia from the discrepancy in eye size. Thus, it may be possible to predict schizophrenia or a borderline mental disorder or even a latent psychic deviance in people showing the ocular symptom but not the psychiatric syndrome.

Regarding the possible etio-pathogenesis of the observed ocular symptom in schizophrenics, it may be 1) an epiphenomenon of a general metabolic and/or endocrine disorder analogous to Graves' disease; 2) myogenic in nature due to a disorder of the neuromuscular system; 3) an interaction of the two; or 4) the result of numbers 1 and 2 but actually affecting each eye differentially.

Psychic unilateral exophthalmos (PUE) may prove significant in developing new research studies of schizophrenia. I plan to replicate this initial research using objective measurements. I also plan to apply the same method of investigation to other psychiatric syndromes. I believe that organic factors of a neurologic nature may be the basic, primary determinants of mental illness in general, of schizophrenia in particular, and of the observed ocular symptom specifically (1).

Northville, Mich.

Questioning Combat Neurosis in Teachers

SIR: I wish to add some perspective to the paper "Combat Neurosis in Inner-City Schools," by Alfred M. Bloch, M.D., Ph.D. (October 1978 issue). Although Dr. Bloch presents the physical complaints of 253 teachers who had been referred for psychiatric evaluation, there was no control sample of physical complaints among teachers not seeking psychiatric evaluation. Considering that the ages in his patient population ranged up to 61, one would expect a significant number of teachers with some physical complaints, particularly when such categories as bronchitis and atherosclerosis are included. This patient population is hardly comparable to young men in their teens and 20s who have been described as having "combat neurosis."

Although he does not clarify what percentage of these teachers were involved in litigation, he mentions among his sources of referral union representatives and attorneys who represented teachers in Workers' Compensation applications.

He fails to consider the effect that the Workers' Compensation system, which introduces such variables as paid sick leave, fully paid lifetime medical care for various medical problems, disability retirement, and a chance to "get back at the system," would have on the presentation of his patients. Some teachers have had serious injuries, and clearly each case needs to be examined on an individual basis, keeping in mind this reminiscence of Dr. Leo Rangell (1): "In military psychiatry of World War II psychoanalytic psychiatrists confronted with the differential diagnosis between neurosis and malingering, underplayed or even ignored the latter, as if it did not exist."

Dr. Bloch Replies

SIR: I acknowledge there was no formal control sample and that this is relevant. A subsequent study is under way that will include controls.

Dr. Hochman's description of sources of referral is misleading. Most of the referrals (85%) were initiated or recommended by other physicians. Years of well-documented chronological medical records antedated the patient's filing any claim. Although the psychiatric evaluation could be construed, in part, as a chance "to get back at the system," the symptoms preceded (often by years) anything that could be so construed.

The extensive medical substantiation also speaks out against this being the product of malingering, although subjective magnification undoubtedly occurred.

I certainly addressed the issue of secondary gain, which is not limited to the factors mentioned by Dr. Hochman. What I learned was that the most significant (conscious and unconscious) aspect of secondary gain is the fact that the disabling illness allows the individual to withdraw from an extremely stressful situation with a minimum of guilt and failure. I determined this, more than "paid benefits," to be a major factor. Any economic benefits that these people receive, almost without exception, do not equal the salary they would have received had they been able to continue teaching.

Since the original study I have evaluated a number of other teachers. My findings, as well as the findings of other physicians who have communicated with me, substantiate the original data and conclusions.

BOOK REVIEWS

A Festering Sweetness: Poems of the American People, *by Robert Coles. Pittsburgh, Pa., University of Pittsburgh Press, 1978, 51 pp., $6.95; $3.95 (paper).*

This little volume could have been written only by Robert Coles. Its unusual name was suggested by a remark of William Carlos Williams, whom Dr. Coles had written about in a thesis as an undergraduate. Dr. Coles and Dr. Williams became fast friends, and Dr. Williams took the young man on his medical rounds on occasion. In a letter describing what he heard from day to day Dr. Williams hoped that the aspiring young doctor would not feel completely removed in future years from the moments of poetry in everyday life. He wrote, "Every day I hear these poor souls . . . talk poems to me. Sometimes I run to my car and write a few of their words down. Not every day, but on a lucky day, two or three times." Dr. Coles remembered these comments about working-class patients and saw that Dr. Williams both loved and disliked, needed and resented, them. Dr. Williams took heartily to their robust, hard-laboring life, "knew many of them to be utterly decent and thoughtful and kind—but also saw the scars, the warts, the mean and callous and hurt and sad side of their condition, the mix he referred to once as a 'festering sweetness.' "

These words fell on receptive ears as Dr. Coles, a young child psychiatrist working as a physician in the Air Force and based in Mississippi, saw the start of "the troubles" and the growing violence. He decided to stay in the South to try to find out how children who come face to face with a serious social and political crisis managed to get along psychologically, managed really to initiate, in the course of their everyday lives, what others have called a moment of historical change.

Although he started out asking "psychiatric questions" of the families he dealt with, Dr. Coles changed because he saw he was fitting their lives into his psychiatric categories and setting severe limits on what he would allow himself to see and to try to comprehend. It was finally a six-year-old black child, he says, who brought him to his senses: "I don't worry, no sir, I don't. I just go ahead past the crowd of people. They're the ones who are worried about me. I'm only worried about them—they must have bad dreams when they go to bed. When I go to bed I say my prayers with my grandmother and she tells me how lucky I am."

What Dr. Coles writes in his book are a number of "rough diamonds . . . not given the important company of symbol, allusion, and metaphor that Dr. Williams could provide. . . . All I have done is listen [and] keep track of what I have heard." Many of the people Dr. Coles worked with have been not only poor but hungry, wretchedly sick, and subject to many indignities, including rats, flies, viruses, and the absence of electricity.

The poems, culled from the even more distressing words Dr. Coles heard, are poignant. They range from the plaint of migrant workers to the productions of little girls to one titled "Growing Up with Love" written by a black mother in a Chicago tenement in 1970. All were heard by a compassionate physician with a feeling for people of all ages who hurt now and who have been hurt. I will not quote from the book—read for yourself. The whole work is only 51 pages long.

F.J.B.

Social Origins of Depression: A Study of Psychiatric Disorder in Women, *by George W. Brown and Tirril Harris. New York, N.Y., Free Press (Macmillan Publishing Co.), 1978, 389 pp., $19.95.*

This important work on social factors in depression appears at a time when most of us are impressed with the role of genetic factors in certain types of depression, the search for biological predictors, and the unquestionable efficacy of psychotropic drugs in the reduction of the acute symptoms of depression and as maintenance treatment. This book alerts us to the fact that depressions, like most medical disorders, occur in a psychosocial context. Using sophisticated methodology, the authors decipher those social factors which lead to increased risk of depression and develop links between social, economic, and cultural systems and their eventual impact on the individual.

The book is based on a study of about 100 inpatients and outpatients and more than 400 women in the communities of the Camberwell area of London and the Outer Hebrides in Scotland. Using various versions of the Present State Examination, Brown and Harris study the development of depressive disorders and their relationship to stress, provoking agents, and vulnerability factors.

This highly readable book integrates intensive clinical studies with an epidemiological approach, thus avoiding the scholarly but sterile content that often characterizes studies of this type. Although the text is filled with tables, statistics, and appendixes, the authors are careful to help the reader translate sociological concepts into clinical realities.

The major findings of the book follow:

1. Depression is extraordinarily common among working-class women in Camberwell, especially those with children at home, but is less common in rural Scotland.
2. Provoking agents influence when depression occurs.
3. Vulnerability factors determine whether the provoking agent will have an effect. These vulnerability factors include absence of a confiding, trusting relationship, particularly with the husband; presence of three or more children living at home; and death of the mother (but not the father) before the age of 11.
4. The effect of the vulnerability factors is additive in the face of a provoking agent (i.e., more vulnerability factors increase the risk of depression).

5. An outside job may reduce the risk of depression in women in the presence of vulnerability factors.

6. Working-class women are at increased risk because they have more vulnerability factors.

The findings of this book will not be accepted without debate and criticism. The high rate of depression found (i.e., 15% prevalence in Camberwell) raises a question about the looseness of the diagnostic criteria. The firmness of the evidence for the distinction between different etiological factors for psychotic and neurotic depression (i.e., psychotic depression is presumably linked to early parental death and neurotic depression to death and separations) must be replicated before it can be accepted. The broadness of the definition of loss or disappointment and, especially, the emphasis on the meaning of the event to the person will raise a question about reliability.

In fact, the controversy has already begun. Soon after the appearance of this book in London, it was the object of an editorial review and a letter in the prestigious British medical journal *Lancet* (1, 2), and soon the equally prestigious *Psychological Medicine* will be publishing a criticism. The full attention of an editorial in a medical journal for a book written by a sociologist and psychotherapist on a psychiatric topic is unprecedented.

The major finding, one that will be remembered, challenged, and studied, is the importance of intimacy as a protection against adversity in the lives of women. Although the link is not developed by the authors, this finding links this epidemiological study to the work of Bowlby, the animal ethologists, and all investigators interested in the importance of emotional attachments and bonds in the lives of people.

Mental health practitioners and sociologists who have always been interested in these issues will want to read this book. However, it should not be avoided by geneticists, biologists, and psychopharmacologists who search for an integrated understanding of human emotions.

Affective Disorders: Drug Actions in Animals and Man. Handbook of Psychopharmacology, Vol. 14, *edited by Leslie L. Iversen, Susan D. Iversen, and Solomon H. Snyder. New York, N.Y., Plenum Press, 1978, 369 pp., $29.50.*

This volume is the fourteenth publication in a remarkable series devoted to neuropsychopharmacology and biological psychiatry. Previous volumes dealt with various aspects of basic sciences, such as neurochemistry and animal pharmacology. The present work is mainly concerned with human and animal psychopharmacology as well as applied clinical research in the area of affective disorders. This book successfully presents new progress in basic research in neuropsychopharmacology and important developments in the pathogenesis and biological treatment of affective disorders.

The volume contains a comprehensive review of the pharmacology of antidepressant drugs, including papers on monoamine oxidase (MAO) inhibitors, tricyclics, and lithium salts. There are two outstanding chapters: "MAO Inhibitors: Animal Pharmacology" by Richard Squires and "Lithium Pharmacology and Physiology" by Nelson Hendler. These are undoubtedly the most valuable contributions of the book. The chapters are well written and offer the reader an updated and comprehensive review of the MAO field.

The chapter on the biochemistry and metabolism of tricyclic drugs by F. Sulser is a good synthesis of current knowledge in this area. It also provides a critical appraisal of the clinical use of antidepressant medication. The chapter on the clinical use of lithium by Baron Shopsin and Samuel Gershon is remarkably clear but perhaps too restricted to the treatment of psychopathological aspects. A discussion of the physiological aspects of lithium in relation to kidney function and thyroid metabolism would be welcome in a work of such high quality.

The last chapter, on lithium prophylaxis and experimental rubidium therapy, is interesting, but too much attention is given to rubidium, a salt of great theoretical interest but little clinical value in the treatment of affective disorders.

This volume brings together important and high quality contributions on basic research and clinical applications in the biological understanding and treatment of affective disorders. It can be recommended for clinicians and researchers in neurobiology and biological psychiatry.

Psychotropic Drugs: A Guide for the Practitioner, *by H.M. van Praag. New York, N.Y., Brunner/Mazel, 1978, 442 pp., $17.50.*

Dr. van Praag is known for his work on the pharmacology of antidepressants and neuroleptics and for his many contributions to clinical psychiatry. He is a versatile and original scientist; his book is provocative, scholarly, and useful for the investigator, the practitioner, and the medical student. The volume also has the advantage of single authorship.

The book is divided into 5 parts and 27 chapters. The first 20 chapters deal with such diverse topics as definition and conceptualization of major mental disorders, the classification of psychotropic agents, and the pharmacology and clinical uses of neuroleptics, antidepressants, and ataractics. Dr. van Praag states that "the schizophrenia concept has no justification" and "sorely needs revision on the basis of empirical psychopathological studies" (p. 166). He proposes a new concept of "schizophrenic psychoses" based on symptomatology, etiology, and outcome.

The author divides depressions into "vital" and "personal." The former correspond to the endogenous and the latter to the exogenous depressions; the term "vital" implies that many psychosomatic functions are depressed. This fact is often overlooked by the clinician, but the question is whether this new terminology has any practical advantage over the traditional one.

Dr. van Praag's use of psychotropic agents is based on the proposition that these compounds do not "respect the boundaries of the conventional nosological entities" and that "the syndrome or symptoms determine the indication" (p. 101). (Lithium, which is specific for mania, is the exception.) However, he does not provide any experimental evidence to prove that his criteria for the prescription of psycho-

pharmacological agents are superior to those based on diagnostic considerations.

The author's attitude toward psychotherapy is traditional. When there is strong evidence that a biochemical error underlies a mental aberration, drugs are the treatment of choice. On the other hand, maladaptive behavior, whatever its cause, necessitates psychological methods of therapy. In certain forms of anxiety ataractics may be prescribed because not all neuroses respond to psychotherapy and because there are "simply not enough trained psychiatrists to meet the demands" (p. 331). A recommendation of this type seems odd, since throughout this book the author emphasizes that pharmacotherapy is not a trial-and-error proposition or a matter of expediency.

Chapter 21 deals with sedatives and hypnotics, a topic that is often neglected in standard textbooks of psychiatry. Most sedatives have become obsolete since the introduction of benzodiazepines in the practice of mental care, but two time-honored drugs, paraldehyde and chloral hydrate, can still be used effectively in some conditions.

Chapter 22 is devoted to the controversial subject of the psychodysleptics. On the basis of extensive clinical experience with LSD and related compounds, the author's position is that these agents have the potential of powerful therapeutic compounds but that more research is needed to dispel current misconceptions about their psychological effects.

Dr. van Praag also deals with the use of drugs in children, in the aged, and in emergency situations. His chapters are succinct and lucid and provide useful guidelines for psychiatrists and family physicians.

One may disagree with some of Dr. van Praag's concepts and clinical points of view. Nevertheless, he must be given credit for his success in breathing new life into a branch of medicine that is relatively young but is already threatened by stagnation and misuse.

Books to Help Children Cope with Separation and Loss, *by Joanne E. Bernstein. New York, N.Y., R.R. Bowker Co., 1977, 232 pp., $13.95.*

The size and scope of contributions to thanatology are growing, and much of the work is becoming monotonously repetitive and even boring. This book focuses on the larger issues of separation and loss as experienced by children in many different ways through their development, such as going to a new school, being hospitalized, moving to a new area, losing friends, getting lost, losing parents through separation, desertion, divorce, death, war, or displacement, and coming to terms with fostering, adoption, and step-parents. There is also a section for those children who remain homeless, although the topic of institutions for children is not directly covered. Bernstein has read and graded 438 children's books dealing in some way with these topics, although a few strange ones, like sex education, manage to creep in. Each book is given a well-written synopsis, a short, critical comment, the ages for which it is appropriate, and the reading level that it requires.

This book is a boon for parents, but child and adolescent psychiatrists will also find it useful to look at these nonclinical presentations of familiar clinical problems and even recommend them to families undergoing a crisis of adjustment. For those who like to include bibliotherapy among their clinical skills, this book should prove a valuable addition to their library.

Cocaine: 1977. NIDA Research Monograph 13, *edited by Robert C. Petersen, Ph.D., and Richard C. Stillman, M.D. Rockville, Md., National Institute on Drug Abuse, 1977, 210 pp., $3.00.*

This monograph presents the history of cocaine, its chemistry (including methods for the detection of cocaine in body fluids), its possible mechanism of action, reports of the experiences of users, and an examination of its abuse potential and its use in medicine. Although each chapter is written by a different author, the editing is well done so that the style is uniform and clear. The perspective maintained throughout is scientific and professional. This is a welcome relief from the bias so often found when one reads about drugs of current social concern. For the reader who wants to know the salient, established facts about cocaine this monograph has no peer.

EDWARD C. SENAY, M.D.
Chicago, Ill.

Interpersonal Psychoanalysis: New Directions, *edited by Earl G. Witenberg, M.D. New York, N.Y., Gardner Press (Halsted Press, John Wiley & Sons, distributor), 1978, 150 pp., $16.95.*

I thoroughly enjoyed reading this fine, small book. It is a heartening illustration of the many avenues of discovery available to an "open" system of psychoanalysis. The papers, which derive from a continuing professional education course presented at the William Alanson White Institute in New York by seven of the senior faculty members, have no unifying theme and do not need one. Each presents the current or matured thinking of its author on a subject of special interest to him or her, and we are fortunate to be able to share their thoughts. The authors are Marianne Horney Eckardt, David E. Schecter, Gerard Chrzanowski, Silvano Arieti, Edgar Levenson, Edward Tauber, and Jerome Singer.

In his lucid introduction Witenberg states a common ground:

> All these authors subscribe to a certain set of assumptions. They would all agree that there are broadening and changing indications for the kind of person to whom psychoanalysis is applicable. What this implies is that treatment must be tailored to the individual. Today's analyst needs to have a flexible approach. As times have changed, so have the problems for which people seek relief. . . . Dreams, bodily sensations, cognitive styles, and values, as well as language, are used to discover the unknown.

For psychiatrists, who are respectful of but not quite intimidated by the complexities of human existence, this volume will be a welcome source book for expanded therapeu-

tic orientations and interventions as well as an example of the good work being done in our field.

ROBERT G. KVARNES, M.D.
Washington, D.C.

Community Mental Health: A General Introduction, *by Bernard L. Bloom. Monterey, Calif., Brooks/Cole Publishing Co. (Wadsworth Publishing Co.), 1977, 316 pp., $10.95.*

There are many books about community mental health, but few are as well written as this one. Bloom has provided an introductory text that is based on a historical perspective and is presented in a highly informative and interesting format.

The book is divided into three major sections: The Development of the Community Mental Health Movement, Community Mental Health in Practice, and Community Mental Health in Perspective. There are also three lengthy appendixes, including President Kennedy's message to Congress and the various titles and regulations of the Community Mental Health Centers Act, Public Law 88-164.

The book appears to be primarily oriented to new students who are interested in continuing in the field or who want to understand how the present community mental health system in the United States came into being and how it developed. Although much of the historical information in the first section can be found elsewhere, the author's ability to write clearly about what can be boring material, particularly regarding the role of the federal government, makes for an exciting and interesting background for what is to follow.

In chapter three in the first section Bloom reviews the Community Mental Health Centers Act as an instrument of social policy. This is a different perspective than one usually finds in books about mental health. Once again, it provides a special opportunity for students and other readers to think about and discuss not only the professional implications but also the social and political context in which community mental health programs function. In this regard, Bloom provides the broader and unique view of the community psychologist. He follows this up with a specific example of the impact of the act on Boulder, Colo., where he teaches. Even those who have never worked in complex social systems will gain a feeling of reality from this approach.

In the second section of the book Bloom deals with such community mental health practices as preventive intervention, mental health consultation, crisis intervention, and the assessment of community structure and community needs. He chooses not to discuss the full panoply of services that community mental health centers provide, and this might be a weakness in the book. However, the areas he does discuss are handled extremely well. For example, preventive intervention is given a base in the public health approach to disease prevention, with an extremely lucid explanation of public health concepts. Real examples throughout these chapters also serve to concretize the reader's perception and memory. Bloom appears to be well grounded in both mental health and public health theory and service as well as in an understanding of community systems. Research findings are used throughout and serve to develop a scientific base for the field.

In the final section Bloom not only gives a number of critical views of the community mental health movement but also stimulates the reader's thinking in a look beyond community mental health. He raises an important research-based question about a future perspective in the field, i.e., whether to focus on individual emotional difficulties or on the broader issues of our environment and society.

This book packs a great deal into a small volume. With its excellent reference section, its many research-oriented statements, and its articulate approach, it has much to offer as an introductory text and as a compact compendium for the mental health practitioner who wants to further his or her understanding of where this major field has been and where it is going.

ARTHUR J. BINDMAN, PH.D., M.P.H.
Boston, Mass.

The Family, Sex and Marriage in England: 1500–1800, *by Lawrence Stone. New York, N.Y., Harper & Row, 1977, 800 pp., $30.00.*

Although not all of us are family therapists, the nature of the family, including the interaction among its members, is of practical concern to almost any psychiatrist whose practice is not made up exclusively of unmarried orphans. This book will help one have a better understanding of families because it provides an understanding of the attitudes, customs, and institutions of society, a prediction of future trends, and a knowledge of the past and of the way today's conditions developed.

Lawrence Stone, Dodge Professor of History at Princeton, traces the evolution of family structure, patterns of sexual behavior, mating arrangements, and child-rearing practices in various social classes over a period of three centuries. From the title one might be concerned that a study of behavior in England would not be applicable to the United States because our population includes not only people of English and Western European heritage but also those of Native American, Oriental, and African background. However, data from colonial America are included, there is no denying the influence of English cultural patterns on the development of the United States, and the author does not overgeneralize. Another concern might be that the study does not include the changes in the nineteenth century of "moral reform" and sexual repression in the Victorian period or the further changes in the current century. Actually, changes since 1800 are discussed in the concluding chapter.

Although some of us may look backward with longing to some aspect of life in the earlier part of this century, few if any would care to live in the society that existed in England in the early 1500s. Social relationships in general tended to be cool or even hostile. The individual had little freedom of choice in marriage, and there was apparently little affection between marriage partners. Partly because of high infant mortality, there was little emotional investment in children. Neither the rich nor the poor had any real privacy within the home, and it was virtually impossible to maintain personal cleanliness (even if one desired it). Things changed, but there was no continuous linear change, nor did changes result from growing technical knowledge, a higher level of civilization, or the democratic spirit alone.

Stone tells us about the changes with meticulous scholarship and ample documentation but in a thoroughly readable style. The psychiatrist reader will find some interesting minor points in addition to the main thesis because the author is well aware of the influence of family life, sexual mores, and

child-rearing practices on personality development and mental health. He notes the types of problems seen by a "psychological practitioner" in the early eighteenth century and tells us about the work of a "prototype of Masters and Johnson" in the late eighteenth century.

One is sure to get some new ideas from reading this account of olden times, and one is almost sure to accept the author's conclusion:

> There is no reason to assume that the end-product of affective individualism, namely the intensely self-centered, inwardly turned, emotionally bonded, sexually liberated, child oriented family type of the third quarter of the twentieth century, is any more permanent an institution than were the many family types which preceded it.

In fact, I think the family may have changed since the last workshop on the family I attended.

MERRILL T. EATON, M.D.
Omaha, Neb.

economically viable and the choice is supported by the prevailing societal ideology. However, they opt for new careers, regardless of their basic characteristics, when career opportunities are limited by economic considerations or by changes in societal ideology. In other words, economic incentives and societal ideology are more compelling for most students than their personal characteristics or original career preferences. The study also found little evidence that either the role models provided by the medical school faculty or curricular changes affect choice of medical career. Finally, the author summarizes findings with regard to the career choices of women and students who choose careers in primary care.

I found it disappointing that the report had so little to say concerning choice of careers in medically deprived areas. However, on the whole this is a timely and valuable text. No physician can afford to be unaware of the issues defined and discussed in the closing chapters titled "Current Issues in Medicine," "The Role of Medical Schools," and "Conclusions."

H. WALDO BIRD, M.D.
St. Louis, Mo.

Medical Students, Medical Schools and Society During Five Eras: Factors Affecting the Career Choices of Physicians 1958–1976, *by Daniel Funkenstein, M.D. Cambridge, Mass., Ballinger Publishing Co., 1978, 221 pp., $16.50.*

This book, written by a premier student of medical students, fittingly caps the author's distinguished career in medical education. It reports the results of a principally prospective longitudinal study of the career choices of medical students and physicians from 1958 to 1976. The author examined data collected on Harvard medical students at matriculation and graduation and as alumni and alumnae in 1974 and 1975, on University of Michigan medical students in the class of 1973, and on a national sample of medical students at matriculation and at graduation in the year 1975. However, at no point is the study's total number of subjects reported; this is a mild disappointment. More to the point, the book is concise and lucid and its text illuminated by 12 figures, 28 tables, and 3 questionnaires. To my delight and surprise, it often provided exciting reading.

The primary objective of the study was to determine the relative importance of various factors, as they changed over five different eras, in the career choices of medical students and physicians. Secondary goals were to identify the characteristics of students and physicians who chose careers in primary care, the characteristics of those who chose to practice in medically deprived geographic areas, and the differences in career choices of women and the factors that influenced them as compared with men. Although he does not explicitly state it as a goal, the author successfully undertakes another noteworthy task. He constructs a working model for making manageable the enormous and unwieldy mass of information available to any investigator on the relationship between the personal characteristics of medical students and their choices of career. He accomplishes this task in chapter one.

The Funkenstein study teaches important lessons to all who would influence the career choice of medical school aspirants, medical students, and physicians. The study makes it clear that medical students are reality oriented. In stable eras, they choose careers congruent with their personal characteristics, but only after determining that the career is

Undergraduate Medical Education and the Elective System: Experience with the Duke Curriculum, 1966–1975, *edited by James F. Gifford, Jr.; William G. Anlyan, M.D., Ewald W. Busse, M.D., and Thomas D. Kinney, M.D., supervising editors. Durham, N.C., Duke University Press, 1978, 243 pp., $9.75.*

This book will not be read in full by many psychiatrists. However, it is of such interest to the small but influential group of psychiatrists who sit on curriculum committees that it deserves to be called to their attention.

In 1966 Duke University School of Medicine introduced a curriculum change that the authors describe as the first new model of medical education responsive to the pressures for change of the 1960s. The new format provided for basic sciences in the first year and clinical clerkships (medicine, surgery, obstetrics/gynecology, pediatrics, and psychiatry) in the second year. The third and fourth years of the medical curriculum were used for elective courses equally divided between clinical subjects and basic sciences.

The chapters of the book dealing with preliminary planning and with the basic sciences are the most dynamic in that they deal with the "turf" questions of whose time was cut. These cuts were not always cheerfully accepted.

As a whole, the style of the book is somewhat turgid and reminiscent of a grant application. The decision to include a chapter on every basic science and every clinical department provides an excess of detail on programs, some of which may not have been altogether innovative. However, it must be acknowledged that individual chapters will be read by chairmen of similar departments. They will be read with interest because it is not always easy to know what is happening in other people's departments unless the familiarity is gained through site visits or similar contact. The specialty chapters on behavioral science and psychiatry are not radically innovative by present-day standards, but they represent a substantial advance from the psychiatric teaching of the 1950s.

Chapters on a number of interdisciplinary programs are provocative. These programs include M.D. with J.D. degrees and M.D. with M.P.H. degrees, medical history, and

biomedical engineering. These programs confirm the fact that Duke allows itself the luxury and the risks of trail-blazing.

On balance, this is a worthwhile book; it emphasizes the fact that the medical curriculum is not graven in stone. Introducing sophomore students to clinical studies is entirely practical, gratifying to the teacher, and probably an excellent idea. Electives in the later undergraduate years lead to some diffuseness but are sensible as a recognition that structure ends with graduation and that holding fast to the student for a few additional months is futile. Basic sciences in the advanced years raises arguable questions about what mix of subjects best prepares the student for the clinical practice of medicine. This in turn raises questions about the respective places of clinical skills and research skills in medical education. The Duke study documents the value of pedagogical experimentation within sensible limits that is carefully monitored for outcome.

ROY CLOUSE, M.D.
Philadelphia, Pa.

The Paranoid Process, *by W.W. Meissner, S.J., M.D. New York, N.Y., Jason Aronson, 1978, 840 pp., $30.00.*

In this work Dr. Meissner investigates both the pathological aspects and the constructive contributions of the paranoid process in human development and the normal organization of social and cultural structures. The book has three major divisions: an opening discussion and review of the literature, a presentation of clinical cases, and an articulation of a clinical theory about the paranoid process.

Among the topics reviewed in the first section are dynamic formulations and phenomenology of paranoia, pathological paranoid syndromes and related psychic states (envy, jealousy, and prejudice), "normal" related states (group formation, belief and value systems), paranoid mechanisms (projection, introjection, denial, paranoid construction), and catalysts of paranoid reactions (loss, depression, narcissistic injury). This review covers the gambit of psychoanalytic thinking and includes selected contributions from such nonanalytic literature as family studies, game strategies, and animal experiments.

In his second section Dr. Meissner presents vivid but wordy descriptions of 10 clinical cases. The variation in pathology in these cases is striking, including patients with acute and chronic schizophrenia; schizoid, narcissistic, and borderline personalities; and "analyzable" neurotic characters with phobic, obsessional, and hysterical features. The common thread in these accounts involves the use of paranoid mechanisms for defense and coping. Dr. Meissner convincingly demonstrates that these mechanisms arise from the matrix of a fairly repetitive family constellation.

For each patient one parental figure was perceived as controlling, powerful, willful, domineering, angry, intrusive, critical, or sadistic. The other parent was seen as passive, helpless, depressed, weak, submissive, masochistic, and victimized. Each patient internalized both figures and reenacted the parental sado-masochistic interaction in subsequent life experience, usually by projecting the sadism onto the external world and identifying oneself with the helpless, innocent victim. Additionally, one parent was usually symbiotically attached to the patient while the other was unavailable and rejecting. This led to an extreme perception of object relationships as either engulfing or abandoning.

In his third section Dr. Meissner returns to clinical and theoretical discussions of such topics as introjection, projection, phobic states, nightmares, narcissism, and the paranoid process in human development. In his formulations he draws heavily on the works of Searles, Kohut, Winnicott, Mahler, Erikson, and Rochlin. The hallmark of this work is thoroughness. This exhaustive review preserves the complexities of the literature. Dr. Meissner summarizes articles rather than merely citing them, thus providing a useful condensation of the overwhelming amount of writing on this topic.

Dr. Meissner's clinical discussions and theoretical formulations clearly support his contention that the paranoid process forms a core of normal and pathological human experience. The only area of confusion, in my view, concerns his discussion of the role of introjection and projection in human development. At times he maintains that these mechanisms serve to differentiate self from object and are therefore fundamental to the establishment of ego boundaries. At other times he indicates that projection and introjection require the previous existence of a certain degree of self-object differentiation in order to operate, thus introducing a contradiction.

My view is that projection and introjection have little to do with the differentiation of inner from outer experience. These mechanisms create an apparent perceptual difference between the "good" introjected object and the "bad" projected object, but this still involves a fusion or de-differentiation of self and object representations, an absence of ego boundaries. However, since these mechanisms serve the pleasure principle, they may be an adjunct to self-object differentiation by reducing anxiety to a "good enough" extent that the normal maturation of the infant's neuronal apparatus can proceed without major disruption. Introjection and projection operate to minimize the intrusions of overwhelming affects on the expanding integrative capacity of the CNS. Thus, I differ with Dr. Meissner's assessment that libido fosters the integration of good and bad introjects but aggression opposes and destroys this union, which constitutes a value judgment for libido and against aggression and overlooks the fact that both are basic and necessary. Love, like hate, can blind one to reality, and any strong drive or affect can be destructive to the formation of psychic structure and object constancy.

The major drawback of this book has little to do with the author's grasp of the issues and the literature, which stands unequaled among that of recent workers in this area. It has to do with size and organization. The book could be far less redundant and half as long without loss of cogency. Dr. Meissner allows too much overlap in his effort to elaborate on all aspects of the paranoid process. The result is a work encyclopedic in quality but formidable in magnitude.

The Community Training Center: An Educational-Behavioral-Social Systems Model for Rehabilitating Psychiatric Patients, *by Michael D. Spiegler, Ph.D., and Haig Agigian, M.S.W., A.C.S.W. New York, N.Y., Brunner/Mazel, 1977, 363 pp., $15.00.*

The rehabilitation of mentally ill patients is an area of American psychiatry that has received little attention. Probably because we are a pragmatic, task-oriented society, we

focus our efforts on etiology and treatment, ignoring partial hospitalization, aftercare, and rehabilitation—measures vitally needed by mental patients. Too few workers in American psychiatry and the mental health professions acknowledge that many mental patients, particularly those who have been hospitalized for a long period of time, have social and other deficits that must be rectified if the marginal individual is to be able to return to a reasonably active life.

This volume describes explicitly a comprehensive program for the rehabilitation of psychiatric patients in a community training center located at the Palo Alto, Calif., Veterans Administration Hospital. The authors developed an educational-behavioral approach in 1969; its specific purpose was to use educational technologies to rehabilitate mental patients. In classrooms, patients learn interpersonal and cognitive skills, community survival skills, health-related skills, and socialization skills. The authors describe various didactic and practice models whereby an individual learns such tasks as how to begin a conversation, use the telephone, budget an income, and live independently.

One of the chapters presents an intensive evaluation of the community training center and the outcomes for the patients who participated in the program during its first few years. Spiegler and Agigian consider the community training center a successful program for "ameliorating some of the misery of psychiatric patients." They also believe that their model can be applied beneficially for socially marginal individuals other than psychiatric patients—the physically handicapped, for example. I recommend this volume as a practical, day-by-day guide for psychiatrists and mental health workers who wish to devote their time and energies to the critically important problem of rehabilitation of the mental patient.

Dying: A Psychoanalytic Study with Special Reference to Individual Creativity and Defensive Organizations, *by Tor-Bjorn Hagglund. New York, N.Y., International Universities Press, 1978, 253 pp., $15.00.*

Dr. Hagglund, a practicing psychoanalyst and training analyst in the Finnish Psychoanalytic Society, provides an excellent review of the literature on psychodynamics of individuals facing death. He also presents five case histories. Using material from these cases as well as his extensive analysis of the poetry of Edith Södergran, Hagglund formulates a description of the interplay among narcissism, phallic defenses, and the process of creativity during mourning.

Basically, when faced with death an individual increases all defenses, particularly denial. Mourning work begins with a decrease of denial, during which the person relinquishes objects, life, and body sequentially. The wish for immortality then leads to the formation of an "auxiliary ego" that maintains object relations after death, or the patient envisions life as continuing in children, work, or accomplishments. Finally, as death progresses, regression predominates and psychic life is regulated by splitting. Emotions and objects are divided into good and bad, with the world to be left as bad and the fantasy of death or of the person's oneness with the therapist (or other human) as good. This dynamic sequence leaves the impression that pathological mechanisms characterize the dying process; generalization from a small sample may have produced this distortion.

The author's prime theoretical contribution is his view of creativity as arising during the mourning process. Mourning is experienced as something unreasonable and possibly unbearable for the dying person's narcissism. The less creative person defends against mourning with phallic narcissistic defenses, which serve as a safeguard against frustrations in human relationships. The creative person, on the other hand, is able to identify with the subliminated form of woman's (mother's) inner space, which enables the individual to expand creatively the two-person relationship. For the nonpsychoanalyst reader the author's adherence to analytic jargon will make comprehension of his theory difficult.

Self-Starvation: From Individual to Family Therapy in the Treatment of Anorexia Nervosa, *by Mara Selvini Palazzoli; translated by Arnold Pomerans. New York, N.Y., Jason Aronson, 1978, 289 pp., $15.00.*

Mara Palazzoli is a classical psychoanalyst who has had years of experience in treating patients with anorexia nervosa through traditional analytic methods. In *Self-Starvation,* however, she advocates a family approach of brief intervention, using largely behavioral methods. The book is in part a historical treatise on the author's journey through the therapeutic maze that has led her to her present approach. As such it is an intriguing confession of an individual who has not compromised objective observation and experimentation by doctrine and who has not been bound by only one conceptual orientation to the phenomenon she observes. Dr. Palazzoli does not dismiss a psychoanalytic approach in attempting to gain a grasp on the developmental psychosexual dynamics of the disorder. Indeed, her work suggests that this approach gives a substantive basis from which to proceed with further experimental models of therapy. This book is not a polemic advocating a single model of approach or explanation of the therapy. Rather, it seems a worthy heir to Dollard and Miller's classic examination of the complementarity of psychoanalytic and behavioral approaches in understanding the human condition (1).

Most important, Dr. Palazzoli comes across in this book as a complete physician. She knows the subject she addresses, anorexia nervosa, and the patients who endure this prototypical psychosomatic disease. She realizes that there is flesh and life involved as well as psyche. She advises the psychiatrist to take cognizance of the body while examining the psyche. In this, she conveys her own competence as a physician as well as a psychologist. Above all, she knows patients and their families.

Dr. Palazzoli came to a family approach to the treatment of anorexia nervosa through the work of Dr. G. Benedetti of Basel in 1967. At that time she established the Milan Center of Family Studies. This work is a review of both her earlier approaches and her later ones. She apologizes for the absence of statistical analyses of her later family approaches. These have recently been published in her book *Paradox and Counter-Paradox* (2).

Self-Starvation, although first published in Italian in 1971, arrives on the American scene along with the work of Hilde Bruch (3) and Salvadore Minuchin and associates (4) as well as Levenkron's novel, *The Best Little Girl in the World* (5). Dr. Palazzoli acknowledges her debt to Dr. Bruch and Dr.

Minuchin and associates, but her work goes beyond both Dr. Bruch's psychological insights and phenomenological observations and Dr. Minuchin's family studies. Dr. Palazzoli's identification of specific communication processes, such as affirmation, negation, and deaffirmation, concepts drawn from Jay Haley's models (6), is especially clearly drawn and presented in recorded excerpts from family therapy sessions.

Although Dr. Palazzoli's presentation has a bit of the enthusiasm of a convert, this does not interfere with the precision of her observations of patients with anorexia nervosa and of their families. The work suffers a bit from the author's still uneven incorporation of existential terms into her more evenly used psychoanalytic vocabulary. This deficiency is less obvious in her latest work (2). What Dr. Palazzoli seems to be achieving in the present work is a synthesis based on the approaches of psychoanalysis, existential analysis, and behavioral theory, including communication theory. More important, the use of these conceptual models is based on the firm foundation of careful observation over many years. A great deal of wisdom will be obtained and synthesized by the reader working through this provocative book.

Notice of Subscription Price Increase

The *American Journal of Psychiatry* has not increased its subscription price to nonmember subscribers since 1974, in spite of substantial increases in a number of areas: printing and mailing costs, cost of paper, size of the *Journal*, including the addition of the Clinical and Research Reports section, size of the staff, and new procedures for the critical review of manuscripts. We have now reluctantly come to the conclusion that a price increase to nonmember subscribers can no longer be postponed. Accordingly, effective March 1, new subscriptions to the *American Journal of Psychiatry* cost $27 a year for domestic subscribers and $35 a year for foreign subscribers, including those in Canada. A single issue costs $3.50 in the United States and $4.25 for orders from foreign countries, including Canada.

OFFICIAL ACTIONS

Fall Committee Meetings

Following is a summary of the proceedings of the fall committee meetings of the American Psychiatric Association, which were held in Washington, D.C., in September 1978.

The Council on Children, Adolescents, and Their Families

EDWARD H. FUTTERMAN, M.D., CHAIRPERSON

DURING the winter of 1978, the Council received 24 volumes in tentative draft form of the Juvenile Justice Standards Project prepared by the Institute of Judicial Administration and the American Bar Association. Major decisions of the project were "to reject the medical or rehabilitative model of the Juvenile Court" and to establish the principle of family autonomy as paramount over the child's best interests. APA urged the American Bar Association to delay approval pending further review. The Council appointed an *Ad Hoc Task Force on the Juvenile Justice Standards Project,* chaired by Frank Rafferty, M.D., which worked rapidly and effectively to prepare a response to the overall thrust of the recommendations and a detailed critique of those volumes about which clinical commentary would be most relevant. The 115-page APA response was approved for transmittal by the Board of Trustees, and a summary of the APA response is being prepared by Andre Derdyn, M.D. Both of these documents are available through the Central Office. The American Bar Association is scheduled to vote on these standards at its February 1979 meetings.

The *Task Force on the Rights of Children, Adolescents, and Their Parents,* Perry Bach, M.D., chairperson, drafted a critique of the Mental Health Law Project *Legislative Guide* section on "Mental Health Treatment For Minors." Viola Bernard, M.D., completed the critique for the Council, which was joined by the American Academy of Child Psychiatry, the American Association of Psychiatric Services for Children, and the American Society of Adolescent Psychiatry in submitting the product to the *Mental Health Disabilities Law Reporter.* In view of the delay by the Supreme Court in handing down a decision on the Parham case and the accelerated activities in many states to introduce a variety of procedures affecting the treatment and hospitalization of minors, the Commission on Government Relations agreed to distribute the Council's critique to the membership for use in dealing with individual state legislatures. In addition, the Council decided that an alternative model statute for treatment of minors, prepared by psychiatrists, was needed to compete with the one developed by the Mental Health Law Project. Therefore, a Task Force on Commitment of Minors was formed, chaired by Michael Kalogerakis, M.D., and charged with drafting a model commitment law for minors. It has begun its work by reviewing the legal and clinical literature pertaining to the rights and needs of children, adolescents, and parents regarding psychiatric hospitalization and reviewing existing state statutes. The task force is at the stage of preparing a first draft of a model statute with commentary.

The *Task Force on Children and Adolescents in State Mental Hospitals,* Paul N. Graffagnino, M.D., chairperson, has completed its survey of all 50 states. The data are being tabulated, examined, and analyzed. A final report on this work is anticipated by the summer of 1979.

The *Task Force on Alternative Patterns of Organization of State Governments to Provide Mental Health Services to Children and Adolescents,* Frank Rafferty, M.D., chairperson, has completed its work. On the basis of surveys and informal information obtained from all 50 states, the task force identified five patterns of organization of child and adolescent services. They could not identify any dynamic flow from one pattern to another or a clear rationale for the choice of a particular pattern by a particular state. A historical review revealed a lack of influence by the child guidance movement and by the mental retardation movement on state departments of mental health. State actions seemed to be more dependent on federal categorical initiatives than on any other variable. Another finding from the report was a steady decline in participation by psychiatrists and other skilled child mental health professionals in state systems. The implications of this report will be studied by the Council for appropriate action.

The Council's statement on Public Law 94-142 (Education for All Handicapped Children Act) has been circulated to all components of APA. The newly formed *Task Force on Treatment and Education,* Irving Berlin, M.D., chairperson, is following up on this issue and collecting information from local groups who are working with schools to identify the problems and possibilities. Since each state must develop its

own plan and there are 20,000 autonomous school districts in the nation, the task force is interested in obtaining information from district branches. They are working not only on the need to amend the law and its regulations but also on its implications for mental health manpower and for training. The task force has also developed a paradigm for distinguishing activities in any setting that would be considered educational as opposed to therapeutic. The financial implications of these distinctions are also being considered.

The *Task Force on Services to Children and Adolescents in Community Mental Health Centers,* David Leaverton, M.D., chairperson, is preparing its final report. This product will include the results of a survey of services to children and adolescents in CMHCs, a narrative description of some successes and failures, a review of the role of child psychiatrists in CMHCs, a review of the standards of care for children, adolescents, and families in CMHCs, and recommendations about federal guideline changes and future federal support.

The *Task Force on Child Psychiatry and Family Practice,* Ruth Lavietes, M.D., chairperson, is nearing completion of its work. The plan to develop a curriculum in child psychiatry for family practice training programs has been abandoned since most programs are not amenable to input from specialties. Therefore, the task force has turned its emphasis to the process of integrating child psychiatric concepts into the training of family practitioners. Recommendations are being formulated regarding education and liaison.

The *Task Force on Teenage Parents and Their Children,* JoAnne Fineman, M.D., chairperson, has begun its work by amassing a comprehensive bibliography and reviewing causes and interventions. Most current programs are embedded in pediatric, medical, church, educational, and casework settings, with very little psychiatric input. No cohesive national policy has emerged. The task force is developing preliminary position papers and educational activities as well as monitoring legislation on teenage pregnancy. The task force is also maintaining liaison with the Coalition for Optional Parenthood Education (Taghi Modarressi, M.D., APA representative).

The Council reviewed work on television and children being done by the American Medical Association, the American Academy of Child Psychiatry, the Group for the Advancement of Psychiatry, Conference on Television and Socialization of Minority Children, PTAs, and NIMH. The Council recommends that APA continue to support the American Medical Association's position on television and violence. Furthermore, the Council asked that the delegates to the Section Council on Psychiatry of the American Medical Association introduce a resolution at the AMA House of Delegates in support of an AMA Conference on Family Violence. In transmitting this recommendation, the Council stressed the need for inclusion of the roles of television and other media in influencing violence in the family.

Due to the lack of integration of family therapy into general psychiatric practice and controversy about the relationship between family therapy and other therapeutic modalities, the Council decided to establish a Task Force on Psychiatry and Family Therapy. The preliminary charge of the task force is to study the clinical indications and contraindications for family therapy, to review the integration of family therapy with other psychiatric therapeutic modalities, and to review issues in training and accreditation in family therapy.

The Council expressed concern about the impact on child development of the variety of family life patterns now emerging, such as single-parent families, father-only families, nonrelated extended families, homosexual parents, etc. The Council proposed a new Task Force on Alternative Family Styles. The preliminary charge was to review the impact of the variety of emerging family life patterns on child development; to identify and review issues of psychiatric concern such as needed services and supports and implications for child custody; to make specific recommendations regarding prevention of child psychopathology, promotion of optimal child development, models of service, and forensic positions relating to custody; and to prepare a position statement on fitness for parenthood. Since the Council on National Affairs also proposed a Task Force on Changing Roles and Family Practices in American Life, it was agreed to merge these two efforts.

The Council also proposed establishment of a Task Force on Clinical Assessment in Child Custody. The preliminary charge was to develop guidelines for practice in custody evaluations, including attention to voluntary and involuntary requests for evaluations, relationship to the courts and other professional agencies, critieria for making recommendations and preparation of reports. At the request of the Reference Committee, the Council agreed to review the draft of the report on child custody by the Group for Advancement of Psychiatry prior to establishing this task force.

In other actions, the Council worked with the Commission on Government Relations on guidelines for national health insurance, the Child Health Assessment Act, and other legislative matters. The Council also participated in the final drafting of the APA position statement on abortion. In addition, liaison has been maintained with the National Consortium on Child Mental Health, the National Institute of Mental Health, and the American Academy of Child Psychiatry. Regarding the latter, the Council worked with Robert Reichler, M.D., in preparing responses to drafts of Department of Health, Education, and Welfare regulations regarding research on children.

The Council wishes to express its appreciation for the support and cooperation of all components of APA in its efforts to integrate child and adolescent psychiatry into the fabric of the organization.

The Council on Emerging Issues

PERRY OTTENBERG, M.D., CHAIRPERSON

THE COUNCIL, which meets three times each year, is presently deeply concerned with a number of major emerging issues:

1. A Task Force on Impaired Physicians will be formed in 1979 and charged with studying the problems, resistances, and delays in obtaining help for impaired physicians, including psychiatrists; paying particular attention to physicians who function in isolated office settings outside of hospital staffs and without frequent contact with colleagues; determining what are the optimal intervention models and confrontational techniques that are useful in helping to get impaired physicians into therapy; and considering whether there is overreliance on the Alcoholics Anonymous model for the treatment of alcoholism in the absence of psychiatric care for impaired physicians. The Council views these as the core tasks; after they have been dealt with, the Council believes that the same or another task force should undertake an assessment of the life experiences that underlie successful mastery of stresses inherent in the physician's role.

2. The Council also proposes to establish a Task Force on Changing Family Patterns in American Life. Interest in the subject is largely an outgrowth of special sessions at the last two annual meetings on the changing roles of males and is also influenced by such factors as the growing numbers of single-parent families, recombinant families (newly divorced, with children, and remarried), dual career families, and increasing numbers of individuals who prefer to live alone.

3. The Council's *Committee on Abuse and Misuse of Psychiatry in the United States,* Eugene B. Feigelson, M.D., chairperson, has formulated a charge for its work:

> The Committee shall receive and evaluate any charges of psychiatry being used for political purposes in the United States; where appropriate, such charges shall be referred to the World Psychiatric Association. The Committee shall also develop and receive instances of individual or institutional misuse and/or abuse of psychiatry in the United States that do not fall under the Ethics Committee (an extension of the intent of a process begun in 1972 by APA).

4. The *Task Force on Psychosocial Impacts of Nuclear Advances* has met several times under chairperson Rita Rogers, M.D. It is currently developing a questionnaire intended to elicit attitudes toward three target groups: the Clamshell Alliance, the "I-don't-knows," and the Committee on the Present Danger. Other major concerns of the task force include educational aspects of nuclear advances, the pervasive secrecy that surrounds the social issue, how terrorism is involved, dehumanization, collective attitudes toward massive death, and personnel problems and nuclear accidents.

5. The *Task Force on Sex Education and Sex Therapy,* Edward Auer, M.D., chairperson, is concentrating on the role of psychiatrists in sex education for medical and graduate students and in continuing education. A survey of directors of residency training has been carried out most successfully. The task force will meet soon in Chicago to consult with leading authorities on sex therapy.

Other concerns of the Council involve ego aspects of death and dying, programs in thanatology, the problems of the chronic mental patient, antipsychiatry groups, the problem of "boundaries" in psychiatry, the impact of *DSM-III* on clinicians and private practitioners, and problems in polarization of the membership.

The Council on Internal Organization

ROBERT O. PASNAU, M.D., CHAIRPERSON

THE COUNCIL met for two and a half days during the September 1978 committee meetings, heard reports from many of its 29 components, and discussed a wide variety of topics. The Council is charged with "all those matters involved in the organizational structure of the Association not covered by Consitutional Committees." It oversees an enormous range of activities including the annual meeting and its programs; advertising in publications; membership benefits, including all insurance plans; prizes and awards; the House Committee, which oversees all elements of the Central Office buildings; the Hospital & Community Psychiatry Service, journal, and Institute; the Committee to Review *Psychiatric News*; and the Committee of Residents. The Council also serves as an overseeing body for the APA staff and the other councils, making certain that they function efficiently and have the support necessary to accomplish their tasks. The highlights of the actions that took place during the September Council meeting will be described in this report.

Morris A. Lipton, Ph.D., M.D., chairperson of the *Task Force to Study the Impact of Potential Loss of Pharmaceutical Support,* announced that his task force had come to some conclusions. It was noted that the net income to the APA from the pharmaceutical industry is about one-half million dollars annually. Most of this amount (approximately $20 per member per year) is derived from advertising in the publications and exhibits at the meetings. Only about $15,000

comes in the form of direct grants and support, mostly for the named lectureships at the annual meeting. The task force recommended "vigilance rather than divestiture." While noting that there is great division in the membership as to the ethical issues involved in the relationship between medical associations and the pharmaceutical industry, the task force recommended that APA should not discontinue pharmaceutical advertising in the publications nor exhibiting at the scientific meetings. However, APA should begin a dialogue at once between the leaders of the pharmaceutical industry and the officers of APA to work toward the elimination of named lectures and funds identified with individual firms; instead, there should be a listing of supporting sponsors in the programs at the meetings. The task force emphasized that this should not be done immediately but only after careful consultation and advice from industry. The Advertising Committee was praised for its pioneering work in monitoring APA advertising, and it was suggested that the committee's vigilance continue in the future. Finally, the task force recommended that district branches and areas follow the guidelines set down by the Board of Trustees. The Council voted to receive the task force report and to present it to the Board of Trustees for action.

Chester Trent, M.D., chairperson, reported on the work accomplished by the *Committee on Professional Liability Insurance*. There has been an improvement during the past year with respect to losses among psychiatrists compared with other specialty groups, and the overall premium rate will increase by not more than 1% this year, compared with 10% or more in recent years. The committee also had considered the problem of claims against psychiatrists involving sexual activity, in accordance with previous instructions from the Board of Trustees, and has developed an exclusion for such coverage. This matter was sent to the Board of Trustees for full discussion of the APA policy and position on this matter.

Christopher T. Bever, M.D., chairperson of the *House Committee*, is also chairperson of the newly established *Building Committee*, which consists of members of the House Committee and staff. The Building Committee was established by the Board of Trustees in May 1978 and is charged with overseeing the purchase of property and construction of APA's new Central Office building. Dr. Bever reported that the committee has been meeting regularly with the architect and others concerned to discuss progress and problems. His report included selection of the architect, purchase of the real property, zoning problems, design of the building, planning of space allocation within the building, parking facilities, and various other aspects of the committee's work.

Charles B. Wilkinson, M.D., chairperson of the *Committee on Grants and Awards*, informed the Council that the Manfred S. Guttmacher Award continues to be in financial difficulty, in spite of the additional funds transferred to its account. The Committee on Grants and Awards recommended that the Guttmacher Award be given only every second year, alternating with the Isaac Ray Award. The Committee on Grants and Awards also recommended that efforts continue to be made to find qualified applicants for the Marie H. Eldredge Award.

Lawrence C. Kolb, M.D., chairperson, presented the report of the *Committee to Review Psychiatric News*. The committee recommended that a membership poll be authorized to make available data on which to base recommendations to improve *Psychiatric News* and make it more attractive to its readership. The committee also asked that a legal opinion be sought as to whether limiting the amount of advertising in *Psychiatric News*, which had been suggested previously, would be found to be restraint of trade. The committee reported that it would recommend no changes with respect to *Psychiatric News* until the membership poll is completed.

The Council heard a report from staff on the advertising survey recently conducted for APA, which led to a renegotiation of APA's contract with Steven K. Herlitz, Inc., its principal advertising representative, and to termination of APA's contract with its other advertising representative, Fred Michalove. The new contract with Herlitz provides for a reduction in the commission rate paid to Herlitz and a new termination clause that is much more favorable to APA than the previous one. The Council agreed that experience with the Herlitz company during the next year would determine whether APA would continue to use the company or hire its own in-house advertising representative.

The *Committee on the Annual Meeting*, William S. Davis, M.D., chairperson, reported that it had received a request to solicit information from members as to their preferences for annual meeting sites. The Council recommended that *Psychiatric News* publish a list of cities where an APA annual meeting would be feasible, indicating advantages and disadvantages of each, and request input from members. This committee recommended to the Council that day-care facilities at annual meetings be discontinued, since they were underutilized and were not cost effective. However, the Committee on Women told the Council that they considered this program important and requested the Council to consider their proposals for a day-care program. As a result, the Council authorized the establishment of a task force to develop a day-care program, which would be expected to become self-supporting once in operation.

Allan A. Beigel, M.D., chairperson of the *Committee on Program*, reported that his committee had received many comments concerning the scheduling of the opening session, convocation, and business session at the annual meeting. Comments were that the opening session was too long, that the convocation was poorly attended, and that the business session tended to interrupt the flow of the scientific program and used space that could be available for scientific sessions. The Council voted to take this question to the Board of Trustees and to recommend that the Board establish a task force or ad hoc committee to explore the alternatives and make recommendations. The Council also recommended approval of the committee's request to schedule scientific program activities on Wednesday evening, the night of the banquet, during the 1979 annual meeting.

The Council again discussed election issues and voted to recommend that establishing election procedures and guidelines and dealing with violations thereof should be made a function of the Board of Trustees itself rather than of a separate committee. The Council recommended approval of a staff request to raise the charge to district branches participating in centralized dues billing from 50 cents per member to $1.00 per member and that a minimum charge of $50 per district branch be established. It also agreed to recommend to the Assembly that fiscal years of district branches be changed to conform to APA's fiscal year in order to facilitate their participation in centralized dues billing.

Richard G. Johnson, M.D., chairperson of the *Committee on Member Life, Accident, and Health Insurance*, reported that the limitation on inpatient psychiatric coverage that had been authorized for one year is working satisfactorily. The Council recommended approval of the committee's request

for a task force, consisting of members of the full committee, to study problems concerned with the definition of "psychiatric illness." Dr. Johnson also reported on a proposal for a national field trial of an insurance coding project, which would use a six-category code instead of *DSM-II*. APA members will be requested to participate in the field trial if their patients agree. The Council recommended establishment of a task force to handle the national field trial. Dr. Johnson also presented a draft of the final report of the *Task Force on Consideration of Problems with Psychiatric Underwriting*, of which he is chairperson. The report will be modified and augmented before being given consideration for publication.

Jack Wolford, M.D., reported to the Council on the activities of the *Committee to Coordinate the Functions of the Hospital & Community Psychiatry Service, Journal, and Institute*, which included recommendations for changes in content and style of the journal and making films and videotapes available to all members of APA, with a lower charge to those who are members of the H&CP Service than to non-Service members.

Dr. Pasnau would like to express his appreciation to Dr. Jack White, staff liaison, Mrs. Patricia Scheidemandel, administrative assistant, Malkah Notman, M.D., Lester Rudy, M.D., Richard Steinhilber, M.D., and Stanley Yolles, M.D., for their enthusiastic efforts.

The Council on International Affairs

ALFRED M. FREEDMAN, M.D., CHAIRPERSON

THE COUNCIL has had an active year, one in which communication among psychiatrists on an international scale has flourished. Joint meetings with our French colleagues were held in connection with the APA annual meeting in Atlanta. Forty-five French psychiatrists and spouses attended the meeting and several joint sessions were held. Then 350 American psychiatrists attended the meeting in Paris, France, planned by the APA task force in cooperation with the Société Medico-Psychologique. Both joint meetings were highly successful.

Our continuing concern with abuses and misuse of psychiatry and psychiatrists has led to the appointment of Drs. Joe Yamamoto, Harold Carmel, and Melvin Lipsett to a subcommittee of the Council to write a proposal about receiving and monitoring complaints of human rights abuses, working with the World Psychiatric Association's Committee on Abuse, and maintaining close and continuing follow-up.

A letter has been sent to the President of Argentina, General Videla, asking for information about psychiatrists and others who have been allegedly arrested in Argentina and held without charges. On November 22, 1978, a telegram was sent to the Supreme Court Chairman in Russia appealing for a reduction in the sentence of Alexander Podrabinek. In addition, APA is an active member of the Human Rights Workshop organized and supported by the American Association for the Advancement of Science's Committee on Scientific Freedom and Responsibility.

The *Task Force to the International Organizing Committee of the 2nd Pacific Congress of Psychiatry*, chaired by Norman Rosenzweig, M.D., is proceeding with plans to hold the 2nd Pacific Congress of Psychiatry in Manila, Philippines, May 11-16, 1980, immediately after the APA annual meeting in San Francisco. Lindbergh Sata, M.D., has agreed to head the program committee for that meeting.

The *Task Force on Transcultural Aspects of Ethnocentricity Among Psychiatrists*, Ramon Parres, M.D., chairperson, will present some of its preliminary findings from its research at the 1979 annual meeting.

The *Committee on Psychiatry and Foreign Affairs*, chaired by William Davidson, M.D., was established in December 1977 to continue the work done by previous task forces concerning foreign affairs in specific areas. The committee hopes to have a meeting of Israeli and Egyptian psychiatrists in Washington, D.C., sometime in 1979. Outside funding is being sought for this project.

APA's representative to the *Inter-American Council of Psychiatric Associations*, Reginald Lourie, M.D., is also its president this year. The Inter-American Council and Dr. Lourie are investigating ways in which satellite communication can be used for program presentations at meetings in Central and South America. Also, the translation of some of the audio tapes from APA's annual meeting into Spanish is being undertaken.

Last year the Council offered complimentary subscriptions to the *American Journal of Psychiatry* and *Psychiatric News* to member associations of the World Psychiatric Association to promote communication. To date we have had replies from 43 countries, and they are now receiving our publications regularly.

During the summer of 1978, we wrote to the chairpersons of the other APA Councils about carrying out joint projects. Many joint efforts are possible: an international meeting on the regulation of research with a special emphasis on human experimentation; an international meeting on psychiatric training standards and certification; a joint project with the Council on Children, Adolescents, and Their Families, since 1980 is the Year of the Child at the United Nations; and input from our Council to the new project on ethnicity under the auspices of the Council on National Affairs. Cooperative projects are needed, and the subjects are unlimited.

Am J Psychiatry 136:4A, April 1979

The Council on Medical Education and Career Development

PAUL J. FINK, M.D., CHAIRPERSON

THE COUNCIL met in May and September 1978. In addition to receiving reports from the components, the Council addressed a variety of programs and issues pertaining to the medical education and career development of psychiatrists.

APA will participate in a consortium, formed under the leadership of the American College of Psychiatrists (ACP), to develop and administer a psychiatric residency in-service examination. Other organizations represented in the consortium are Ohio State University (which has developed an examination program and computerized techniques for analyzing and reporting scores), the American Association of Directors of Psychiatric Residency Training (AADPRT), and the Association for Academic Psychiatry (AAP). The American Board of Psychiatry and Neurology (ABPN) will be represented by a nonparticipant observer.

The in-service examination is a pilot project to include 50 resident training programs selected on the basis of the willingness of the total resident population to participate. The program will utilize the current content areas of the ABPN written examination. The Council underscored the differences in the objectives of the in-service training examination and the ABPN certifying examination. The former provides assessment of resident performance and assistance in remediation and serves as part of preparation for certification, and the latter provides certification of competence.

APA has authorized the Office of Education to develop a consultation system in program planning, development, implementation, and evaluation for psychiatric residency training directors. While this service will not guarantee future accreditation and/or NIMH grant funding, it will provide assistance to program directors in various aspects of educational needs. The program will be self-supporting through fees paid by the training program directors, working collaboratively with the consortium of psychiatric education organizations. The office has solicited names of psychiatrists to serve as consultants to the program from a consortium of psychiatric education organizations and the NIMH psychiatric education branch. The Council is currently developing guidelines and procedures concerning confidentiality, consultant selection process, reimbursement procedures, performance evaluation, and progress reports. It is anticipated that the program will be operational in late 1979.

The APA Board of Trustees at its May 1977 meeting charged the Council to develop guidelines and procedures for renomination of current directors for reelection to the American Board of Psychiatry and Neurology (ABPN). The Council reviewed the present process, the recommendations of Ad Hoc Committee on Implementation of the 1976 Referenda on the ABPN, and the reports from the liaisons to the ABPN.

The Council recommended that renomination for reelection should not be automatic and that the director's performance should be evaluated informally with consideration given to participation in committees and activities of the ABPN and APA, most notably the Task Force to Facilitate Communication Between the APA and the ABPN. Incumbents may also be asked to respond to questions prepared by the APA Board of Trustees. Further, the directors eligible for reelection to the ABPN should be renominated according to their performance. The Council reaffirmed its previous recommendation to suggest that the ABPN study the issue of the present system of tenure and consider a possible six-year term for directors.

In 1976, the APA Board of Trustees referred the planning and development of the next decade conference on psychiatric education to the Council. The most recent conference was held in 1975; preparatory components met in 1974. The Council, after reviewing the history of previous conferences, recommended that a steering committee, including members of the Council and other appropriate APA components and the Assembly, officers, and representatives of major psychiatric education organizations (including Canadian groups), oversee the development and implementation of the conference, with the Office of Education coordinating staff support.

The Council reviewed correspondence concerning education in drug and alcohol abuse, geriatric psychiatry, and care of chronically mentally ill patients and referred these content areas to the undergraduate, graduate, and continuing education components.

The Council noted that concerns regarding these areas extend beyond education to issues involving service delivery and research, which are the responsibility of other councils, and suggested that coordination of all deliberations and recommendations take place at the level of the Reference Committee.

The Council discussed the need for a component to address issues of manpower distribution, utilization, and deployment. There is need to study manpower issues extensively, but there is no separate component that addresses these issues exclusively. APA staff have attempted to coordinate documents, articles, information, and other data, as well as responses to regulations concerned with manpower.

The Council noted that it has the responsibility to coordinate data collection and dissemination concerning manpower and recommended the founding of a separate task force to develop guidelines for data collection on manpower issues, to review and synthesize data contained in the report of the President's Commission on Mental Health, the Graduate Medical Education National Advisory Council (GMENAC), the Council of Medical Specialty Societies (CMSS), the Mendenhall study of physician activities, and other such studies, and to advise APA on approaches to future manpower studies. Such a task force could also serve as an advisory group to professions involved with data collection on psychiatric manpower for APA.

Nancy Roeske, M.D., reported on reorganization of the Section Council of the American Medical Association (AMA) and noted that the activities of the specialty section councils have been transferred to the aegis of the medical specialty societies. The AMA has responded to a number of resolutions from the section councils and plans to sponsor a national conference on the chronic mental patient within the year.

The Council has been asked to develop a plan for liaison activities between APA and the section council. Since Dr. George Pollock, who chairs the section council, is a member of the Committee on Graduate Education and Dr. Roeske is

a member of the section council as well as this Council, both can provide direct liaison.

Nancy Roeske, M.D., APA representative to the AMA Inter-specialty Advisory Board (IAB), reported that the AMA wishes to increase its cooperation with specialty societies in areas of continuing education. As part of these expanded activities, the IAB has requested that 1) each specialty society nominate a person to be a representative to the AMA Council on Continuing Physician Education, and 2) specialty societies alert their members to the fact that the AMA desires a wide variety of specialists to participate in its scientific meetings.

The AMA has also been concerned with the complex issues involving mandatory continuing education, certification, and recertification. There are particular problems for the large number of physicians who do not have initial certification. Many states are considering the possibility of demanding participation in specialty recertification programs or successful completion of a general "recertification examination" or "relicensure examination" developed by the states as a requirement for reregistration of licensure. This could create a two-class system of certification/recertification, as well as duplicate efforts or requirements.

The Council reviewed Public Law 92-603. The regulations to implement Section 227 of the Social Security Amendments of 1972 may restrict teaching physicians, who function as supervisors of residents, from billing Medicare on a fee-for-service basis.

The Council discussed the personnel section of the President's Commission on Mental Health report and the report of the DHEW task force concerned with implementation of the recommendations contained in the President's Commission report. Staff coordinated suggestions in preparing a response. In addition, the Council and staff will continue informal communication with the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) to follow up on these recommendations and their proposed implementation.

The guidelines for EEG of the American Electroencephalographic Society (AEEGS) were referred by the Medical Director to APA components for study and comment. Although the development of standards for diagnostic testing extends beyond the Council's charge, the Council noted several concerns including quality control and educational objectives.

The Council supported collaborative efforts with the Council on International Affairs in substantive educational areas and noted the degree of interest abroad in the entire field of psychiatric education, including evaluation of training, certification, and recertification. The Council suggested additional areas for joint efforts including international education programs, standards for educational content and program quality, evaluation of foreign medical graduate applicants prior to training, and study of education experiences of medical students in other countries who wish to enter psychiatry.

The Council is working with the Council on Mental Health Services and its Task Force on Emergency Psychiatric Care Issues to address the educational aspects of emergency psychiatric care. Dr. Gail Barton, member of the task force, has developed a set of protocols, as has the Canadian Psychiatric Association, which will be reviewed by the Council and appropriate components. The Council suggested that components include the following topics on their future agendas: 1) the availability of psychiatrists in emergency room settings to teach as well as provide service; 2) curricula in psychiatry for training emergency room physicians; 3) learning experiences for psychiatrists who work in emergency rooms; 4) standards for psychiatric services in emergency rooms of general hospitals; and 5) the role of behavioral scientists other than psychiatrists in providing emergency care.

An APA Falk Fellow represented the Council during the spring meeting of the Residency Review Committee for Psychiatry and Neurology (RRC). The Council views this as important and suggested continued representation by the senior Falk Fellow on the Council while recognizing that the degree of participation is the prerogative of the RRC.

The report of the *Commission on Certification in Administrative Psychiatry* was given by Thomas T. Tourlentes, M.D., in the absence of Dean K. Brooks, M.D., chairperson. The Commission proposed an educational retreat to continue the discussions initiated during the July 1978 meeting. The retreat will provide an opportunity to clarify the commission's purposes, objectives, role, and activities and to develop strategies for more effectively implementing the Commission's charge. The Council concurred with these plans. The Board of Trustees reversed its earlier action to terminate the Commission in May 1980. The Council recommended change in status to a permanent committee with established membership.

The Council reviewed the administrative psychiatry examination procedures. The oral examination has been conducted in hotel guest rooms, a practice that the Council believes is inappropriate. The Council recommended that the oral certifying examination be conducted in public meeting rooms or in other appropriate facilities. Since this will increase the cost, the APA staff will work with the Commission to develop cost accounting for the resulting candidate fee increases. The Commission will develop a pilot written examination to be given to candidates in May 1979. Since it is experimental and will require further evaluation, this examination will not enter into the grading of candidates at this time.

APA will cosponsor an Invitational Conference on Administrative Psychiatry in November 1978 under the auspices of the Albert Einstein College of Medicine.

Gary Tucker, M.D., chairperson of the *Committee on Graduate Education*, reported that the Residency Review Committee for Psychiatry and Neurology has prepared a draft revision of the "Guide" and "Essentials" of residency programs in psychiatry. The committee, joined by Dr. William Webb, chairperson of the RRC, discussed these documents in detail (comments will be forwarded directly to Dr. Donald Langsley, a member of the RRC coordinating the revision).

The Council discussed the PGY-1 (first postgraduate year in psychiatry). The Liaison Committee on Graduate Medical Education (LCGME) has the final authority for accrediting and developing policy concerning PGY-1 experiences in medicine as a whole. The Council felt that APA, through the Committee on Graduate Medical Education, should review the first graduate year educational experiences and make specific recommendations for psychiatry. These could be transmitted to the LCGME through the RRC and the Council on Medical Specialty Societies (CMSS) for use in LCGME deliberations.

The Council also asked the committee to discuss at its next meeting the content and process of graduate education concerning the care of the chronic mental patient, geriatric psychiatry, and education in alcohol and drug abuse.

Leroy T. Levitt, M.D., vice-chairperson of the *Subcommittee on Foreign Medical Graduates*, recommended to the Council that the various APA components on foreign

medical graduates be consolidated into one group to address the variety of issues related to foreign medical graduates, including education, manpower, career activities, deployment, and service delivery. This recommendation was supported by the Council, the Task Force on Foreign Medical Graduates, and members of the Council on National Affairs during a joint meeting. This newly proposed committee could serve as a resource body to consider matters of current and future legislation affecting foreign medical graduates, problems of acculturation, credentialing, licensure, education and training, continuing education and career development, practice setting, etc. Therefore, the Council also recommended that the Subcommittee on Foreign Medical Graduates be discontinued.

Larry Silver, M.D., chairperson of the *Committee on Medical Education*, presented a paper, "The Role of the Admissions Committee in Assessing the Mental Health of Medical School Applicants," written by the committee for proposed submission (contingent on APA approval) to the *Journal of Medical Education*. The Council requested that the committee prepare a revision of the paper for further review and comment.

The committee also discussed possible future agenda items including 1) an expansion of the study of admissions committees with a specific case example format; 2) a study of mental health issues of medical students, focusing on the mental health problems of medical students, effects on student functioning, and the preventive, supportive, and treatment resources needed by medical schools (the committee and Council considered the possibility of a task force to explore these issues in more detail and to make recommendations on the types of services needed); 3) a study of the undergraduate medical student curriculum, focusing on content areas (chronic mental patient, alcohol and drug abuse, geriatrics, and primary care); 4) a study of factors related to specialty selection by medical students, particularly in terms of understanding what might be done to increase the numbers of students entering psychiatry; and 5) a study of the benefit of the one-year fellowship in psychiatry for third- or fourth-year residents in other specialty areas.

Robert L. Leon, M.D., chairperson of the *Committee on Continuing Education*, recommended a special meeting to review continuing education requirements for APA members. The need for a more in-depth response to these members was discussed in light of the first three years' experience and their relationship to the requirements of other medical specialty societies.

Additionally, the committee noted the need for an extensive discussion of issues of credentialing and accreditation in continuing education and a review of the issues raised by the Assembly Area V Action Paper, "Mandate for the Study of Appropriate Continuing Medical Education for Psychiatrists."

The *Task Force on Self-Study Materials and Audio Tapes* and the *Task Force on Continuing Medical Education Exemptions and Exceptions* were formed during the past year. Since there is considerable overlap in the work of the two task forces and that of the Committee on Continuing Education, the Council approved a recommendation that the task forces report directly to the Committee on Continuing Education to provide integration and consolidation of efforts and present policy recommendations.

The Council endorsed the recommendation of the committee and task forces that APA should develop appropriate self-study materials for APA members for Category I. They noted that such materials will be particularly useful for disabled members, members who live in rural or isolated areas or in foreign countries, and others for whom continuing education programs are less accessible or who prefer to enrich their on-site learning with participation in self-study learning programs. The Committee on Continuing Education will be responsible for planning and developing guidelines for design, implementation, funding, and production of such materials.

The Council also endorsed the recommendation of the committee that APA not endorse the self-study learning packages or series (such as a journal club, subscription series or psychiatric update, etc.) currently being developed by various representatives of industry, noting that these materials are often superficial and must be purchased by subscription rather than by topic only. While the Council endorsed APA work with industry or outside organizations to prepare and publish in-depth self-study materials that address specific topics, APA must maintain complete control of the contents and these materials must be available to members on an individual package basis.

The Committee on Continuing Education reviewed two self-study pilot projects submitted by Audio Digest and AV/MD into Category I self-study packages. Although the committee noted that these did meet the requirements for Category I, the committee felt these proposals did not provide a sufficiently intensive study of a topic area and recommended rejection of these proposals. However, the Council instructed the committee to provide written feedback to both companies, describing the specific differences in the content areas and making suggestions for an improved format. The Office of Education staff will work with the committee and with these companies to see if appropriate learning packages can be developed on a pilot basis.

The *Task Force on Self-Study Materials and Audio Tapes*, Layton McCurdy, M.D., chairperson, reported on the development of guidelines and procedures for self-study materials, including audio tapes. To improve the quality of audio tapes, the task force proposed increased collaboration with representatives of commercial firms that tape sessions at the APA annual meeting.

Two members of the task force (including the chairperson) will meet with representatives of the APA Program Committee and the appropriate commercial audio tape firms (currently Audio Digest and AV/MD) to review the final draft of the APA Scientific Program and to select sessions to be taped at the APA annual meeting. The Office of Education staff will attend such meetings at no cost to the Council. Prior to the meeting, the task force will develop guidelines for taping sessions. An editorial review panel will be selected to assist the task force in the review of audio tapes. This panel will review tapes and materials and use a review process similar to that of the *American Journal of Psychiatry*. Consistent with the APA policy of not paying for members' participation at the annual meeting, funding will not be provided for travel expenses. Since neither honoraria nor consultation fees can be provided, the Council requested that their work be given public recognition in some way.

The *Task Force to Consider CME Exemptions and Exceptions*, Eugene Feigelson, M.D., chairperson, held its first meeting in September. To facilitate members' compliance with the APA continuing medical education requirements, the Council concurred with the task force proposals that quality self-study materials be available for APA members who do not have reasonable access to continuing medical education experiences (e.g., rural or foreign members or members who are ill, disabled, or otherwise housebound or

who prefer to use self-study materials as an adjunct to their continuing education activities).

The Council noted that the function of the continuing education requirement is to encourage members to become and remain up to date in their practice activities and concurred with the task force that Board certification provides a measure of professional competence in psychiatry and should be recognized in lieu of one portion of the continuing education requirement. Thus, the Council will recommend that 50 hours of Category I credit should be awarded for becoming certified by the American Board of Psychiatry and Neurology or the Royal College of Physicians and Surgeons—25 credits for Part I and 25 credits for Part II. In addition, psychiatrists who became APA members after July 1, 1976, have a full three years from date of membership to complete the CME requirement.

The task force studied requests for Category I credit for sabbatical activities and concluded that sabbaticals should not qualify for any special educational credits, since members on sabbaticals will have many opportunities to obtain the required Category I credit during the three-year reporting period. In addition, the task force felt that researchers and administrators can find appropriate continuing education activities in the existing categories and do not necessarily require special exemptions. The task force requested that staff carefully monitor the CME reports of the APA members residing outside of the United States and considered the possibility of recommending the use of self-study educational materials for Category I as a more suitable alternative.

The task force suggested that there should be a mechanism for reviewing appeals stemming from rejection of applications for exemptions or exceptions from the CME requirements and recommended that such appeals be processed by the Committee on Continuing Education. Staff were requested to monitor and report data on reported Category VI activities (meritorious learning experiences) to assist the task force in developing standards of acceptability and quality control.

The *Committee on Psychiatry and Primary Care Education,* F. Patrick McKegney, M.D., chairperson, discussed the recent emphasis on increased primary care education for medical students in, among other documents, the Report of the Institute of Medicine (IOM). The committee felt that this emphasis provided a major opportunity for American psychiatry but expressed concern that there was no psychiatrist on the IOM committee authoring that report.

The committee recommended that a policy statement stressing that medical student curriculum include consultation-liaison psychiatry be transmitted to the appropriate national medical-psychiatric education organizations. Similarly, the committee discussed the recent emphasis on an increased need for psychiatrists who relate to primary care medicine as described in the ADAMHA Manpower Task Force Report. The Council concurred with the committee that a policy statement stressing that all psychiatric residency programs include significant, supervised experience in which the resident functions as a consultation-liaison psychiatrist in an ambulatory care setting should be transmitted to the appropriate national organizations.

The committee discussed APA's role in fostering the career development of psychiatric residents in working with primary care physicians and recommended to the Council that a fellowship program similar to the development of psychiatrists having a major commitment to teaching patient care in primary care settings be developed. These fellowships would be given to residents in psychiatry and primary care fields for a two-year period. The educational program would include at least one meeting yearly of at least two days' duration and a funded faculty of primary care physicians and consultation-liaison psychiatrists.

The Council endorsed the concept of such a program and requested that the Committee on Psychiatry and Primary Care Education explore methods of development and implementation for the next Council meeting.

The committee has a variety of continuing liaison activities with APA components, including the Committee on Syllabus for PKSAP-IV, the Committee on Graduate Education, the Task Force on Psychiatric Emergency Care, and the Committee on the Chronic Mental Patient, as well as with such other organizations as the American Academy of Family Physicians. The committee also heard from the chairperson of the Committee on Liaison with the American College of Physicians, who reported that liaison with the American College of Physicians (ACP) has not been optimal. The Council and the committee encouraged CMSS delegates to work informally with the ACP and encouraged the Medical Director's office to continue active contact with the Executive Director of the ACP. Staff also was instructed to continue follow-up work on the liaison activities with the American Academy of Family Physicians.

The Council charged the committee to include in future deliberations discussion about education concerning chronic mental patients, geriatric patients, and drug and alcohol abuse.

The *Task Force on Recertification,* Herbert Pardes, M.D., chairperson, reported on preliminary plans for an intricate system that deals with the process of recertification and utilizes multiple approaches and methodologies. An extensive discussion ensued concerning the relationship of this task force to the American Board of Psychiatry and Neurology (ABPN) and its Subcommittee on Recertification in Psychiatry, the American Board of Medical Specialties (ABMS), the APA Assembly of District Branches, and other groups.

The Council postponed action on the preliminary plans and requested the task force chairperson to discuss these directly with the ABPN subcommittee and focus on the relationship to the guidelines and standards for recertification of the ABMS.

The task force plans to maintain dialogue with appropriate components of the Association through a variety of activities at the 1979 annual meeting, including the development of an issue workshop, preparation of materials on recertification to be incorporated with the Office of Education exhibit, and participation in the meetings of continuing education coordinators, district branch presidents-elect, and district branch newsletter editors, as well as preparation of articles for *Psychiatric News* and the district branch newsletters.

The *Task Force to Facilitate Communication Between APA and the ABPN,* Chester Pierce, M.D., chairperson, reported action items for the American Psychiatric Association as well as for the American Board of Psychiatry and Neurology. The Council noted that the total report reflected the substantial recent move forward in the relationship between APA and the ABPN. Among the topics included for review by the ABPN are matters related to the quality of examiners, the concept of regional examinations, feedback from examiners and candidates concerning their experiences in, and feelings about, the examination process, and a possible additional yearly meeting of ABPN, APA, and other relevant national organizations to encourage dialogue about the activities of the ABPN.

Lindbergh Sata, M.D., submitted a request on behalf of

the Committee on Asian-American Psychiatrists to develop a study of the performance of foreign medical graduate psychiatrists compared with American medical graduate psychiatrists on the ABPN examination. The study would also consider location of residency training (for example, university-based compared with other training facilities) and other factors influencing the quality of graduate education. The Council endorsed the task force recommendation that Dr. Sata meet with Dr. Donald Langsley (chairperson of the ABPN Research and Development Committee) to explore the possibility and methodology of the study.

The task force recommended that APA designate a facilitator to expedite APA members' complaints or problems regarding the ABPN. The Council was sympathetic to the concept and suggested that APA encourage members to communicate with APA but noted that designation of an official facilitator could appear to interfere with the autonomy of the ABPN, particularly if the facilitator were given responsibility for specific follow-up actions. Both the task force and the Council complimented Dr. Lester Rudy, the Executive Director of the ABPN, on the high quality and quantity of communication with candidates and encouraged APA staff to continue to respond to correspondence directly, as well as to communicate with the task force on concerns raised by APA members.

The task force asked the Council to determine what APA might do to encourage more APA members to become Board certified. The Council requested that the chairperson write to the Speaker of the Assembly to inquire how the Council can assist the Assembly on this issue.

The Council congratulated Dr. Pierce on the progress of the task force and thanked him for his excellent efforts. The Council noted with regret Dr. Pierce's retirement from the ABPN when his second term is completed (December 31, 1978) and wished him well in future activities. Dr. Marc Hollender will assume position as chairperson of the task force on January 1, 1979.

Robert Seidenberg, M.D., chairperson of the *Task Force on the Curriculum of Psychology of Women and Men,* reported on its progress and presented an outline of the proposed curriculum, indicating that the current plan was more extensive than orginally intended and that the project may result in a detailed monograph. The Council reviewed the outlines of the curriculum and the monograph, as well as the timetable for completing the project, and expressed some concern over the proposal, noting that this might be an overwhelming task which could not be completed within a reasonable time. The Council requested that the task force prepare several sample chapters of the monograph for its review. Drs. Roeske and Oken agreed to serve as Council liaisons to the task force and to review the draft materials in advance of the spring Council meeting.

The *Ad Hoc Committee for the Implementation of the 1976 Referenda on Psychiatric Certification,* Leigh Roberts, M.D., chairperson, presented the preliminary data gathered from the Membership Survey on Board Certification.

The data analysis on approximately 1,500 charts of tabulations and cross-tabulations is not complete. The Council voiced concern about the storage and utilization of this material by APA components and external groups, noting that issues of confidentiality, legal and financial implications, and staff requirements to maintain these data should be considered in determining policy for its utilization. The Council requested that the Office of Education prepare guidelines for internal and external utilization of these materials for review.

The Council noted that the preliminary data may be very useful to the American Board of Psychiatry and Neurology (ABPN) during its November policy meeting and requested that the Executive Committee during its September 9-10, 1978, meeting approve release of the preliminary data (consisting of frequency counts and percentages) to the ABPN for internal use only.

The ad hoc committee presented an outline for a proposed special session during the APA annual meeting in Chicago in May 1979. The Council endorsed the program and suggested that the committee consider the inclusion of a discussant representing the public to address concerns about the certification process, the adequacy of uncertified physicians, as well as provide an additional perspective to the session. The ad hoc committee expects to complete its work by May 1979.

The Council on Mental Health Services

J. M. STUBBLEBINE, M.D., CHAIRPERSON

THE COUNCIL has been noted for being busy, and the year 1978 set a high mark for activity and productiveness. As a result there have been some changes in the structure of the Council, with several new committees and task forces and charges. Because of a palpably diminished interest in or pressure around national health insurance, the Council was able to devote a good bit of attention to things other than simply the financing of mental health services.

The most interesting development is a Task Force on Aging that has been appointed by the Council on the advice and with the consent of two other councils. There appears to be considerable sentiment within APA for the evolution of a separate council on aging. It was felt that the quickest way to begin was to appoint a task force that would make a statement regarding the appropriateness of a committee or council structure within APA. The task force, chaired by Russell Barton, M.D., has prepared proposals for presentation to the Reference Committee in February 1979.

After searching consideration and analysis the Reference Committee approved the creation of a Committee on Rehabilitation. This has been approved by the Board, and Bertram Pepper, M.D., is chairperson. It promises to be a very active committee and will put APA in contact with many important organizations and federal agencies. It is expected

that the committee will also be making presentations to the APA membership that will be of clinical importance. One possible topic is "The Disability Process," in which psychological antecedents to accidents can be seen, identified, and sometimes dealt with before an accident or disability occurs. There is also a belief that a series of psychic states accompanies any physical disability, and knowledge of such states by the psychiatrist will allow him or her to be of greater help to physically disabled patients.

Another area of much interest and importance is the field of community mental health programs. The Council appointed a Task Force on Community Mental Health Programs to work with a similar component in the Assembly. This task force met, reviewed its charge, and is embarking first on liaison with the Assembly task force and after that with important governmental agencies and personnel in Washington. The focus of these meetings is to begin to collect data on the process of quality determination and evaluation of function of the community mental health centers. It will focus especially on the role and function of the psychiatrist in community settings.

With the termination of the Task Force on Substance Abuse in the Council on Research and Development and with stimulation from many sources within APA, a new Task Force on Substance Abuse was formed, a charge from the Council was drafted, and a report is expected to be made by the task force one month before the Council's fall meetings in 1979. The charge is to address itself not just to alcoholism but other substances of abuse and to determine APA's and individual psychiatrists' proper roles with regard to these vexing major social problems.

Yet another area of progress within the Council has been the emergence of a *Task Force on Psychiatric Emergency Care Issues,* Gail Barton, M.D., chairperson. This task force has been very active for well over a year in maintaining APA liaison with the AMA and emergency room physicians. The task force has spent most of its energy and attention assisting in the development of a curriculum and accreditation mechanism for emergency paramedic training programs. In December 1978, the Board of Trustees agreed to be one of seven sponsoring organizations in the ensuing accreditation programs.

The *Committee on Financing Mental Health Care,* Jay S. Reibel, M.D., chairperson, is studying the implications of mental health benefit packages of various levels that may be offered in proposed bills on national health insurance. The members wish to see an up-to-date utilization and cost data base developed from which there can be good projections of the cost of any proposal. The committee is working in particular with APA's consultant health economist, Mr. John Krizay, and the Joint Commission on Government Relations.

The *Committee on Peer Review,* Henry Altman, M.D., chairperson, continued its difficult and demanding work on a revision of the *Manual on Psychiatric Peer Review,* which will include, in addition to revisions of current material, the report of the Task Force on ECT, the new Federal Employees Program (FEP) guidelines, the psychopharmacology criteria sets, perhaps something from the CHAMPUS guidelines, material from the (non-APA) Committee on Adolescents and the Long-Term Hospital Patient Committee. In addition, there may be revisions submitted by the American Psychoanalytic Association and the American Academy of Child Psychiatry. Even though the current criteria sets are recognized by many as too general, the committee has decided not to change the criteria sets at this time, expecting that a more complete revision will be necessary when *DSM-III* is finalized.

A task force of the APA Commission on Standards of Practice and Third-Party Payment assisted the Blue Cross/Blue Shield Federal Employees Program to revise their claims review guidelines. Mr. Richard Leuhrs, BC/BS FEP Program Director, reported in September to the Committee on Peer Review that the revised guidelines had been distributed to about 70 participating Blue Cross plans in early August. Mr. Luehrs expressed appreciation for APA's assistance and emphasized the importance of liaison between district branch peer review committees and local Blue Cross/Blue Shield plans.

Dr. O. B. Towery, ADAMHA, attended the committee's meeting and reported that DHEW has given a contract to the American Association of PSROs for the purpose of revising criteria sets developed by the various specialty societies that were contracted by AMA to do such work two years ago. AAPSRO will be in touch with about six or eight specialty societies, including psychiatry, to revise their criteria sets. Dr. Towery reported that last year there was some question about the viability of the PSRO system, but at this point its future appears healthy. The APA has suggested several members to serve as consultants to this project.

The *Committee on Federal Government Health Services,* Col. John R. Rogers, M.D., chairperson, is concerned about the quality of service and retention of psychiatrists in the Veterans Administration and other federal agencies. The Council expects to receive a detailed report, with suggestions for appropriate action, sometime during 1979.

As requested by the CPHA and authorized by the Board, the *Task Force to Consult with the Commission on Professional and Hospital Activities,* Henry Pinsker, M.D., chairperson, has provided psychiatric consultation to the Commission and assisted in ensuring inclusion of some psychiatric diagnoses and minimal criteria in the present program. The task force hopes to be involved in the development of the next Quality Assurance Monitor Program.

Am J Psychiatry 136:4A, April 1979

The Council on National Affairs

FRANK M. OCHBERG, M.D., CHAIRPERSON

HAROLD VISOTSKY, M.D., retired as chairperson after three outstanding years. The principal activities and accomplishments of this Council continue to occur within the several committees and task forces. Three new task forces were formed: the Task Force on Psychiatric Aspects of Terrorism; the Task Force on Gay, Lesbian, and Bisexual Issues; the Task Force on Multi-Ethnicity and Cultural Psychiatry. Plans to transfer the Committee on Confidentiality to a new Council on Law and Psychiatry were approved. The Committee on Comprehensive Health Planning has designed a task force, funded for action in 1979, to educate district branches. Thus there have been several significant changes in the content of Council activity, but there has also been continuity of effort addressing the needs and concerns of minority groups and women in psychiatry.

Several new procedures have been instituted. All voting members are assigned to assist two or three components and to review and approve budget requests. Falk Fellows and APA/NIMH Fellows are assigned to and assist Council members in the supervision of components. Fellows may also work intensively with one of the Council components. A caucus of minority and women committee chairpersons will meet during the fall committee meetings and again during the annual meeting. The observer-consultant will focus attention on this caucus and the cross-cutting issues that affect the minority committees.

The caucus of minority committees consists of the chairpersons of the minority committees, the Committee on Women, chairperson and vice-chairperson of the Council, the APA Deputy Medical Director for Minority Affairs, and the observer-consultant to the Council. It is the intent of this caucus to identify issues of concern to the minority components and to advance these issues through collaborative action. The following issues were highlighted:

The *Committee on Spanish-Speaking Psychiatrists* expressed its concern about the Bach-y-Rita case, which involved a charge of discrimination in relation to a faculty appointment. The Council asked the Executive Committee to request that the Commission on Judicial Action review the facts and consider the possibility of entering the case as amicus curiae. Members of this caucus agreed as individuals to be available to form a support group. Action was to be deferred pending communication and approval of Dr. Bach-y-Rita and his lawyer.

Believing that there may be serious slippage in the momentum of affirmative action programs, particularly in medical schools as a result of the Bakke case, the caucus asked the Deputy Medical Director for Minority Affairs to collaborate with her counterparts at the Association of American Medical Colleges and collect and distribute statistics noting the trend in admissions of minority students and women to American medical schools. The caucus will review the statistics and suggest future actions.

Members of the caucus are concerned about the possible demise of the APA/NIMH Fellowship Program, which they view as an erosion of affirmative action in the Association. The caucus recommended APA support for this program, regardless of the availability of federal funds. They also recommend a letter-writing campaign by chairpersons of departments of psychiatry and relevant APA components to the Administrator of the Alcohol, Drug Abuse, and Mental Health Administration and the Director of NIMH, promoting the continuation of this fellowship program.

The caucus encourages the appointment of highly qualified women and minority members to APA components and will identify such individuals to the President-Elect.

The *Committee on Indian Affairs,* Johanna Clevenger, M.D., chairperson, assisted in publication of the *White Cloud Journal,* which will include an abridgement of an exhaustive survey of Indian health services. The committee also planned a field trip to the Chicago Urban Indian Center to coincide with the annual meeting and located a full component of American Indian members and focused on concerns of Indian psychiatrists rather than issues in psychiatry affecting Indians. The Committee on Indian Affairs will now be called the Committee of American Indian and Alaskan Native Psychiatrists.

The *Committee on Asian-American Psychiatrists,* Lindbergh S. Sata, M.D., chairperson, initiated an in-depth survey of Asian women psychiatrists. The project is currently awaiting approval from the Council on Research and Development. The coordinator of the project is Dr. Elizabeth Chan Small from Boston. The committee also participated in the planning of a project to develop a culturally relevant minority psychiatric curriculum. This project, headed by Dr. Albert Gaw from Boston, has been approved for funding by NIMH. An analysis of Asian psychiatric performance on specialty certification with the American Board of Psychiatry and Neurology is being coordinated by Dr. Sata. The committee arranged to house the Asian-American Psychiatric Newsletter in the Menninger Foundation. It will be coedited by Dr. Normund Wong (Topeka, Kans.) and Dr. Luke Kim (Davis, Calif.), with publication scheduled for 1979.

The *Committee of Black Psychiatrists,* Mae McMillan, M.D., chairperson, continued to address itself to the issues of mental health care for the black populations. Major educational efforts for 1978 included the development of the Solomon Carter Fuller Lecture and a special session, "Mental Health Care of Black Americans," which were held at the annual meeting. Dr. Jacqueline J. Jackson, a medical sociologist, the recipient of the Fuller Award, delivered the lecture, "Epidemiological Aspects of Mental Illness Among Aged Black Women and Men." The committee generated a position statement on affirmative action and one on the Joint Conference Committee. The latter is in substantial agreement with the statement of the Massachusetts District Branch. Other significant issues addressed included 1) minority recruitment for medicine and the specialty of psychiatry, and 2) the development of a Division of Minority Mental Health Programs in NIMH. The committee has established active liaison with other APA components and the Black Psychiatrists of America. These efforts yielded significant contributions to the President's Commission on Mental Health, the development of a proposal for the Academy on Issues in Psychiatry for Black Populations, and activities related to support for the ratification of the Equal Rights Amendment. The goal of previous efforts of the committee was recognized in the appointment of a committee to survey

psychiatry services for black South Africans and the actual survey conducted by the appointed group. This activity stemmed from concerns that the Committee of Black Psychiatrists forwarded to APA's Board of Trustees, concerns that have come to be known as the "Bradshaw Memorandum."

Plans for the 1979 annual meeting call for the delivery of the Solomon Carter Fuller Lecture by Eleanor Holmes Norton, Director of the Equal Employment Opportunity Comton, Director of the Equal Employment Opportunity Commission, and an evening panel on politicization of psychiatry.

The *Committee on Spanish-Speaking Psychiatrists*, Angel Gregorio Gomez, M.D., chairperson, obtained a new census of 2,500 Hispanic psychiatrists, encouraged Hispanic psychiatrists to participate actively within their district branches in order to promote organized voting power, joined with other minority committees in the Council to obtain fair representation in the Assembly, moved for a commitment from the Council and APA in the Bach-y-Rita case, anticipating similar cases to be faced in the near future, participated in the planning of a workshop to develop a model curriculum on Cultural Issues in Psychiatric Training for U.S. psychiatric residency training programs, and joined efforts with ASPIRA, COSSMHO (Coalition of Spanish-Speaking Mental Health Organizations), and MALDEF (Mexican American Legal Defense and Educational Fund, Inc.) in order to help the Hispanic Americans to meet their most pressing needs.

The committee's plans for the 1979 APA annual meeting in Chicago include a special session titled "Psychiatry: Relevant for Hispanics in the 80's?" an issue workshop titled "The Spanish-Speaking Women Psychiatrists: A Dual Minority," and the 1979 Simon Bolivar Lecture to be given by Dr. Karl Menninger.

The *Committee on Women*, Elaine Hilberman, M.D., chairperson, continued efforts to mobilize active APA support for ERA ratification and to recommend educational strategies that sensitize the membership to the psychological consequences of sexual inequality. Then, it met to organize a broad educational program about women for the Chicago meeting and initiated efforts that yielded a revision of APA's position statement on abortion and drafted new positions on child sexual abuse and patient package inserts. The committee recommended that APA participate in ERA Mail Day, child-care at annual meetings be continued with a new coordinating structure, the new component on substance abuse include women participants and a focus on substance abuse by women, the report on the chronic mental patient include a family inpact statement, and all proposals concerning insurance coverage for mental disorders be evaluated for possible sex bias against women as providers and consumers of mental health services. Concerns about the representation of papers by and about women and the absence of a blind reviewing procedure in the *American Journal of Psychiatry* continue as unresolved issues. Pending issues include women and substance abuse, home births, elderly women, and a nonsexist language policy for APA journals and scientific meetings.

The *Committee on Comprehensive Health Planning*, Howard Gurevitz, M.D., chairperson, in cooperation with the APA Division on Government Relations and Office of Comprehensive Health Planning, prepared testimony for hearings on the renewal of Public Law 93-641 (the Health Planning and Resources Development Act), prepared formal comments on numerous DHEW regulatory proposals, and coordinated legislative/regulatory activities with other major professional associations. The committee sponsored/conducted a session at the 1978 annual meeting in Atlanta—"Psychiatric Participation in Mental Health Planning." A chronic mental patient policy statement, "A Call to Action for the Chronic Mental Patient," was sent to the committee's district branch liaison for use in review of the long-term care component of Health Systems Agencies plans, and a health planning workshop was conducted for Area II in conjunction with the Area II Tenth Biennial Meeting in New York City. The committee also developed and submitted a proposal for a workshop on current issues in mental health planning for the APA 1979 annual meeting in Chicago and maintained a liaison network with APA district branches concerning health planning matters.

The *Committee on Confidentiality*, Jerome S. Beigler, M.D., chairperson, prepared a Model Law on Confidentiality that has been accepted by APA (see the January 1979 issue of the *Journal*). Other activities of the committee included giving testimony before congressional subcommittees on various confidentiality-related issues, consulting on *DSM-III*, which resulted in Axes IV and V being used only for educational and research purposes, consulting on the CHAMPUS Peer Review project and registering strong objections about certain confidentiality aspects, preparing a statement on the Tarasoff decision, working in cooperation with Jay Cutler and the Joint Commission on Government Relations regarding various confidentiality-related issues in Congress and government agencies, and coordinating activities and legislative interventions with the National Commission on the Confidentiality of Health Records.

The *Task Force on Manpower and Foreign Medical Graduates*, Leroy P. Levitt, M.D., chairperson, studied the impact of Public Law 84-484 on foreign medical graduates in psychiatry and, in conjunction with the Subcommittee on Foreign Medical Graduates within the Council on Medical Education, developed a plan for a Committee on Foreign Medical Graduates. This plan has been approved by the Council and forwarded to the Reference Committee.

The *Task Force on Ecopsychiatric Data Base*, Jay Shurley, M.D., chairperson, after five years concluded an exhaustive literature review, produced an annotated bibliography, and submitted a final report. The final products have been approved by the Reference Committee for publication and sale to the membership.

The *Task Force on Psychiatric Aspects of Terrorism*, Elissa Benedek, M.D., chairperson, identified ethical concerns for psychiatrists who collaborate with law enforcement agencies that respond to terrorist events, identified researchable issues relating to victims of hostage incidents, sought and received a request for collaboration from the Research Committee of the Cabinet Committee for Combating Terrorism, and requested and received approval for outside funding from this group.

The *Task Force on Gay, Lesbian, and Bisexual Issues*, James A. Paulsen, M.D., chairperson, designed a questionnaire based on a similar instrument prepared by the American Psychological Association that, after approval by the Council on Research and Development, can be used to assess the attitudes of APA membership to training, research, and clinical work affecting the purview of this task force.

The *Task Force on Multiethnicity and Cultural Psychiatry*, John P. Spiegel, M.D., chairperson, planned its first meeting to explore tentative goals, which include assembling curricula and other educational materials from existing multiethnic training programs in order to prepare a model training program.

Am J Psychiatry 136:4A, April 1979

The Council on Professions and Associations

WILLIAM R. SORUM, CHAIRPERSON

DISCUSSION AND ACTIONS took place at three Council meetings in 1978—at the annual meeting in May, at a special meeting on June 24–25, and at a meeting on September 7–8. The Reference Committee meetings in June and December also involved the Council.

Many activities included in or implied by the charge to this Council have been assumed or duplicated in recent years by other components, liaison persons, APA staff, or combinations thereof. In the fall of 1977, therefore, the Council decided to make an in-depth review of its functions and to consider options for redirecting its efforts and/or eliminating redundant activities. During the 1978 discussions, two views developed: 1) that the Council was anachronistic, no longer cost-effective, and should be abolished, with its functions being distributed to other staff and membership groups in APA; and 2) that the Council should continue, with a revised charge that would emphasize active monitoring of and liaison with other organizations important to psychiatry and mental health. In support of the latter view, the Council made an inventory of such organizations and drafted a new charge:

> It is the responsibility of the Council on Professions and Associations to monitor and report on the activities of the many associations, organizations and agencies engaged in the common effort to advance the mental health of citizens or whose sphere of activities may have significance for psychiatric patients and psychiatrists. In addition, where appropriate, the Council may maintain liaison with organizations or may monitor the liaison activities of other components of the APA. This includes, but is not limited to, the areas of psychology, social work, nursing, religion, rehabilitation, regulatory agencies and certain social agencies.
>
> The Council's function is to develop recommendations for the APA's position in relation to these organizations and issues that pertain to them.

In its June and December meetings, the Reference Committee took the position that a decision on the future of the Council should be made following a review of all APA components—to begin in February 1979—which will be made by the Board of Trustees' Ad Hoc Committee to Study Councils and Components.[1] Specifically, the Reference Committee delayed approval of the revised charge for the Council until a full discussion of liaison activities is held in February 1979, set aside a suggestion by the Council that there be a task force to study the quality and effectiveness of liaison activities, and recommended against assigning the Ad Hoc Committee on Interprofessional Services to the Council, pending a determination of the Council's future.

The *Committee on Liaison with the American College of Physicians* will present several proposals to the Executive Director of the American College of Physicians. Depending upon the outcome, future liaison may take place at a component or staff level.

The *Committee on Liaison with the American Hospital Association* recommended support from APA for an amendment, prepared by the American Hospital Association, to the Community Mental Health Centers Act.

The Council recommended development of liaison with the American Anthropological Association and also recommended that staff explore the possibility of participation in the National Coalition for Disease Prevention and Environmental Health. APA has received a number of commendations for reestablishing a Committee on Psychiatry and Religion that will focus on liaison activities.

The *Task Force to Formulate Guidelines for Psychiatrists Working with Paraprofessionals* presented a draft report to the Council and the Assembly, and comments have been received from a number of district branches and APA components; the proposed guidelines are being revised and will be resubmitted to the Council.

A draft statement on criteria for involuntary hospitalization was prepared by the *Committee on Psychiatry and the Law*. An ad hoc committee, comprised of representatives of the Commission on Judicial Action, the Committee on Psychiatry and the Law, and the Joint Commission on Government Relations is presently making additions and revisions to the statement. It is hoped that this much-needed document will be ready for approval by the Assembly and Board of Trustees in 1979.

The key consideration now is the outcome of discussions of the Ad Hoc Committee to Study Councils and Components and the Reference Committee; both committees will review the scope and functions of the Council on Professions and Associations along with those of other APA components.

[1] At its February 2, 1979, meeting the Reference Committee recommended that the Council on Professions and Associations be dissolved. The Board of Trustees, at its February 23, 1979, meeting terminated the Council with thanks.

The Council on Research and Development

LESTER GRINSPOON, M.D., CHAIRPERSON

THE COUNCIL met three times during 1978—in April, during the annual meeting, and during the September committee meetings. During the year various Falk Fellows and NIMH Fellows attended meetings of the Council.

Following the recommendation of the Council and the Reference Committee, the Board of Trustees accepted the report on confidentiality by Drs. Jacob J. Lindenthal and Claudewell S. Thomas. It was suggested that Drs. Lindenthal and Thomas publish the full report, which is quite lengthy, and that they submit a 20-page abstract of the report for consideration for publication in the *American Journal of Psychiatry*. Because the Council continues to believe that there is a need for ethical guidelines in regard to role conflict, it voted to recommend that the Task Force on Abuse and Misuse of Psychiatry in the United States further consider this issue. The Reference Committee at its fall meeting approved this recommendation.

After reviewing its work for another year, the Council decided that the Committee on Substance Abuse was not appropriately placed in the Council on Research and Development. It was therefore recommended that this committee be dismissed with thanks and that the Reference Committee consider whether it might be wise to organize some kind of component on drug abuse and place it in a different council. During the spring meeting, the Reference Committee created the Task Force on Substance Abuse and placed it within the Council on Mental Health Services.

The *Task Force on Biofeedback,* Martin T. Orne, M.D., chairperson, has nearly completed its review of research results on biofeedback. This report, which will pay particular attention to clinical applications of biofeedback, will be completed in time for the spring meeting of the Council.

The *Task Force on Electroconvulsive Therapy,* Fred H. Frankel, M.D., chairperson, completed the revision of its report after it was considered by the Council, the Assembly, and a group of ECT experts from this country and abroad. The Board of Trustees, after considering the final report at its meeting in Atlanta in May, accepted it for publication. It is now available from the APA Publications Office as Task Force Report 14.

The *Task Force on Research on Aging,* Carl Eisdorfer, Ph.D., M.D., and Lissy F. Jarvik, Ph.D., M.D., chairpersons, has revised the preliminary draft of its report and a final draft should be available to the Council by the time of its spring meeting.

The *Task Force on Late Neurological Effects of Antipsychotic Drugs (Tardive Dyskinesia),* Ross J. Baldessarini, M.D., chairperson, is completing a draft of its report, which will deal with the current state of knowledge regarding etiology, incidence, prevalence, diagnosis, treatment, and prevention of these disorders. The report will be ready for the Council's consideration by the time of the spring meeting in Chicago.

The *Task Force on Nomenclature and Statistics,* Robert L. Spitzer, M.D., chairperson, continued its work toward the completion of *DSM-III.* In addition to making revisions of the *DSM-III* draft, the task force conducted a field study to attempt to determine the degree of acceptance of and the kinds of problems generated by *DSM-III* among a sample of those using the new nomenclature in the field. While the Council was aware of the existing bias in the sample, it was encouraged by the results of this survey.

Because of a crescendo of criticism of *DSM-III,* particularly for its paucity of psychodynamic material, it was decided to hold a one-day meeting during which members of the task force, the Council, and the Ad Hoc Committee of the American Psychoanalytic Association on *DSM-III* would exchange views. The whole day was devoted to this on September 8, 1978, and a better understanding of the issues and the differences was arrived at. At the conclusion of this meeting, the Council instructed the task force to emphasize the tentative nature of the diagnostic criteria and their potential for abuse in their discussion of the Diagnostic Criteria Section of *DSM-III.* In addition, it was recommended that the wording of part of Chapter II of the January draft be changed so that a diagnosis may be made in the absence of criteria; thus, the ultimate decision regarding any diagnosis is left to the discretion of the treating physician. Furthermore, the Council moved to endorse the compromise with the Task Force on Confidentiality regarding Axes IV (Psychosocial Stressors) and V (Highest Level of Adaptive Functioning); these axes will be considered supplemental, i.e., to be used for purposes of research and education. The Reference Committee during its November meeting further voted to direct the task force to include a 20-page (approximate) appendix that would be aimed at helping psychoanalysts and psychodynamically oriented psychotherapists use *DSM-III.* The timetable for *DSM-III* is such that approval by the Council, the Assembly, and the Board of Trustees should be completed by June 1979.

The *Task Force on Guidelines for the Protection of Human Subjects in Psychiatric Research.* Donald F. Klein, M.D., chairperson, in addition to developing the guidelines, has devoted a great deal of time and energy to monitoring new government regulations of psychiatric research. It has formulated responses to a number of recent DHEW research guidelines because the Council believes that this growing emphasis on regulation will have a chilling effect on psychiatric research. The Council agreed to recommend to the Reference Committee that some kind of standing component be created to monitor this activity and to provide input to governmental bodies developing legislation and regulations concerning psychiatric research.

The Council, believing that it was time for the American Psychiatric Association to join other professional organizations in supporting a policy of decriminalization of marijuana, developed a decriminalization statement to take the place of the 1969 Position Statement on Marijuana. The new position statement was accepted by the Reference Committee and by the Board of Trustees and, with some modifications, by the Assembly.

In response to the request from Dr. Michael Gluck of the Food and Drug Administration that APA undertake the development of safety and performance standards for ECT devices, the Council voted to create a task force for the development of these standards, the *Task Force for the Development of a Safety and Performance Standard for ECT Devices.* Richard D. Weiner, M.D., Ph.D., has accepted the

task force chair, and the task force has begun to develop these standards.

Over the course of the year, the Council reviewed six questionnaires that were to be sent out to the membership, approving some and disapproving others.

The Council was requested to reestablish the Task Force on Lithium Therapy in view of recent findings indicating nephrotoxicity of lithium. However, the Council felt that while studies in this area should be encouraged, there are not enough data at the present time to justify the establishment of a task force. The Council agreed that it would reconsider the issue at its fall meeting in 1979.

Alcoholism Clinical and Experimental Research

The Official Journal of the American Medical Society on Alcoholism and the Research Society on Alcoholism, Component Members of the National Council on Alcoholism

Alcoholism is a complicated disease touching on a multiplicity of disciplines—biochemistry, physiology and pathology of various systems, especially the gastrointestinal and nervous systems. Most physicians are confronted with some aspect of alcoholism in their day-to-day work. Thus, there is a definite need for an authoritative and regular source of vital information on specific laboratory and clinical problems, and on the resources now available to the physician for the treatment of the disease. *Alcoholism: Clinical and Experimental Research* is a practical and multidisciplinary quarterly publication, providing a fresh contemporary approach to what can be done, and what is being done about this complex medical problem.

Psychoanalysis of Drug Dependence

The Understanding and Treatment of a Particular Form of Pathological Narcissism

By J. WINSTEAD ADAMS, M.S.W., Ph.D.

This book is a clear, thorough and sensitively nuanced presentation of theoretical advances and explication examining the causes of chemical substance dependency and its treatment. The author bases his report on years of practical experience in treating hundreds of drug and alcohol dependent persons with a variety of treatment methods. The book outlines a psychoanalytic model of the etiological constructs of chemical substance dependency. Further, it presents a systematic methodology for adapting psychoanalytic techniques to the unique problems encountered by the analyst in treating drug (including alcohol) dependent patients whose underlying problems are related to their pathological narcissism. The author demonstrates that dependence upon drugs in such patients is a symptom of the underlying pathological narcissistic constitution.

1978, 352 pp., $23.50 ISBN: 0-8089-1148-1

The Alcoholic Marriage Alternative Perspectives

By THOMAS J. PAOLINO, JR., M.D. and BARBARA S. McCRADY, Ph.D.

Carefully distinguishing the facts from theories and myths, *The Alcoholic Marriage* is the only comprehensive work to approach this subject from an alternative theory perspective. Its discussion of the alcoholic marriage from four distinct perspectives—psychoanalytic, sociological, behavioral, and systems theory—provides advanced clinicians, researchers, and students with a choice of models of human behavior which can be used alone or in combination with other approaches. The book presents the most complete review available of the behavioral literature on alcoholic marriage, both from a clinical and theoretical standpoint. Drs. Paolino and McCrady firmly refute the notion that people who are married to alcoholics tend to be psychologically disturbed people. The authors cogently argue that the misuse by non-psychoanalysts of psychoanalytic concepts has led to oversimplified and inaccurate theories such as the "disturbed personality hypothesis" and the "decompensation hypothesis" of alcoholic marriage.

Currents in Alcoholism Volume 6

Editor: MARK GALANTER, M.D.

Treatment, Rehabilitation, and Epidemiology is the focus in this volume. The first section deals with the important issue of alcoholic patients in the general hospital with particular attention on the application of the NCA diagnostic criteria to these patients, and on counseling consultation on general medicine wards. Examined is the transition to ambulatory care, in relation to adaptive difficulties and subjective symptomatology. Also discussed is the role of abstinence in the treated alcoholic and the relative importance of abstinence.

breaking
through

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL® 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked
agitation with depression

dual-action®
Triavil
containing perphenazine and amitriptyline HCl

MSD

DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

This is probably your first look at

Actual case photographs by Theodore Spagna.

Photographs of a normal subject experiencing a night of sleep.

ight of sleep

The photographs above reflect 15-minute intervals in a night of sleep at home. This "sleep portrait" is extraordinary because time-lapse photography, available since the 1880's, has never before been used to objectify human sleep. This innovative technique is less expensive than sleep laboratory evaluation, and paves the way for future field research. In the home, the intervalometer-controlled camera captures many naturalistic features of sleep behavior available only to direct observation; the rich behavioral data it records serve to complement those of the sleep laboratory, and may prove to have important significance in sleep research. This is a first step toward an ethology of sleep; it represents the joint efforts of Allan Hobson, M.D., and Theodore Spagna, photographer, sleep researchers at Harvard University.*

*Hobson A, Spagna T: Time-lapse photography and the ethology of sleep. *Sleep Res* 5:210, 1976.

Please see following page for a summary

ROCHE

Take a closer look at...

DURATION OF SLEEP LONGER: 7 TO 8 HOURS, ON AVERAGE

...as proved by nightlong electrophysiologic evidence of increased total sleep time in insomniac subjects in eight sleep laboratory studies.[1]

ASLEEP FASTER: ON AVERAGE, WITHIN 17 MINUTES

...as proved in the same eight studies.[1] Of the hypnotics studied, only Dalmane (flurazepam HCl) improved all three parameters: sleep induction, number of nighttime awakenings and total sleep time.

LONGER EFFICACY: 28 CONSECUTIVE NIGHTS

...of relief from chronic insomnia, as proved in one study using an original 47-night protocol[2] and confirmed in another.[3] (Prolonged administration, though seldom necessary, should be monitored by periodic blood counts and liver and kidney function tests.)

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).
Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit initial dosage to 15 mg to preclude oversedation, dizziness and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies. Periodic blood counts and liver and kidney function tests are advised during repeated therapy. Observe usual precautions in presence of impaired renal or hepatic function.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting daily dose of 75 mg is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a-day dosage schedule. If the once-a-day schedule is employed the maximum recommended dose is 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 mg, and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg and 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 mg doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN Oral Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 mg doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

Announcing a Special Issue of **The American Journal of Psychiatry** *on*

DEPRESSION and ALCOHOLISM

This mid-April special issue, included in regular subscriptions to the *American Journal of Psychiatry,* focuses on two topics of intense concern to the psychiatric profession: depression and alcoholism.

Containing 30 original articles, it covers the spectrum of diagnostic considerations, treatment, management and complications, etiology and phenomenology. The emphasis throughout is clinical. While several articles explore new work on alcoholism and on the relationship between depression and alcoholism, current studies on depression dominate this valuable collection.

Partial List of Topics

Diagnosis

Depression simulating organic brain disease — diagnosis and lithium treatment of manic-depressive disorder in the retarded — delineation of an MMPI symptom pattern unique to lithium responders

Treatment, Management

Depression treated with imipramine and ECT — possible cardiovascular effect of lithium — lithium maintenance: factors affecting outcome — efficacy of drugs and psychotherapy in the treatment of acute depressive episodes

Etiology, Phenomenology

Life events at the onset of bipolar affective illness — childhood depression: interpersonal interactions and depressive phenomena — drug abuse among alcoholic women — psychiatric problems in women during alcoholic detoxification — life events, coping, stress, and depressive symptomatology

A special Guest Editorial by Morris A. Lipton, Ph.D., M.D., provides a unifying perspective to this special issue.

Extra copies of the April 1979 Special Issue (the 2nd April issue) will be available at $3.50 (domestic), $4.25 (foreign). *Payment must be included with order.* Order from:

FLORHENAZ
PROLIX

The Prolixin® (Fluphenazine) system of schizophrenia management—

spanning virtually every clinical situation

There is scarcely a patient-type presenting with schizophrenia that cannot be successfully managed with one of the numerous forms of Prolixin (Fluphenazine).

For the newly admitted, agitated patient, a first choice would be short-acting Prolixin Injection (Fluphenazine Hydrochloride Injection USP).

For long-term management of more "dependable" patients, you have the titration flexibility of four potencies of Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP).

For patients who "cheek" or otherwise resist tablet medication, you can utilize pleasant tasting, orange-flavored Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP).

For long-term maintenance of less compliant patients, you can employ unique, long-acting Prolixin Decanoate (Fluphenazine Decanoate Injection) and achieve effective neuroleptization for up to four weeks and longer with a single injection.

See next page for brief summaries

PROLIXIN® (Fluphenazine Hydrochloride)
TABLETS/ELIXIR/INJECTION

Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP) provide 1, 2.5, 5, or 10 mg fluphenazine hydrochloride per tablet. Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP) provides 0.5 mg fluphenazine hydrochloride per ml (2.5 mg per 5 ml teaspoonful) with 14% alcohol by volume. Prolixin Injection (Fluphenazine Hydrochloride Injection USP) provides 2.5 mg fluphenazine hydrochloride per ml; it contains 0.1% methylparaben and 0.01% propylparaben as preservatives.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine hydrochloride and other antipsychotic drugs is not known.

Periodic checking of hepatic and renal functions and blood picture should be done. Monitor renal function of patients on long-term therapy; if BUN becomes abnormal, discontinue fluphenazine. "Silent pneumonias" are possible.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence. However, gastritis, nausea and vomiting, dizziness, and tremulousness have been reported following abrupt cessation of high dose therapy; reports suggest that these symptoms can be reduced if concomitant antiparkinsonian agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. The incidence and severity of such reactions will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an anti-parkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema, with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines.

For full prescribing information, consult package inserts.

HOW SUPPLIED: *Tablets*—1 mg in bottles of 50 and 500; 2.5 mg and 5 mg in bottles of 50 and 500 and in Unimatic® single-dose cartons of 100; 10 mg in bottles of 50 and 500. *Elixir*—in bottles of 473 ml (1 pint) and in 60 ml dropper-assembly bottles with dropper calibrated at 0.5 ml (0.25 mg), 1 ml (0.5 mg), 1.5 ml (0.75 mg), and 2 ml (1 mg). *Injection*—in multiple-dose vials of 10 ml.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg fluphenazine decanoate per ml in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine decanoate and other antipsychotic drugs is not known.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. Muscle rigidity sometimes accompanied by hyperthermia has been reported following use of fluphenazine decanoate. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an antiparkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. SQUIBB® "The Priceless Ingredient of every product is the honor and integrity of its maker."™

The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

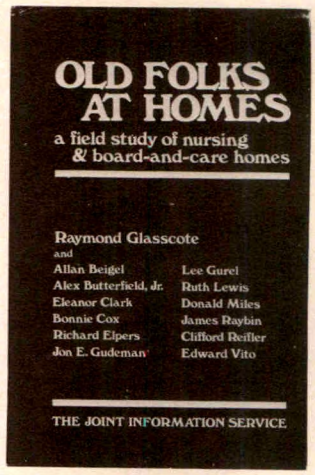
Focus on the Elderly

This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."



190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

proven antianxiety

"Highly specific calming action virtually free of unwanted side effects: this was the remarkable clinical promise of Librium (chlordiazepoxide HCl). And today this promise continues to be fulfilled in a wide variety of patients you see every day.

ROCHE

The published record on Librium is enormous. So large, in fact, it had to be put into a computer data bank and retrieval system. It's a record that shows Librium is highly effective in relieving anxiety; that Librium is seldom associated with serious side effects; that Librium rarely interferes with mental acuity at proper doses; that Librium is used concomitantly with primary medications. However, as with all CNS agents, patients should be warned against hazardous activities requiring complete alertness, and about possible combined effects with alcohol.

performance

Librium® (IV)
chlordiazepoxide HCl/Roche

5mg, 10mg, 25mg capsules

synonymous with relief of anxiety

- ☐ An unsurpassed safety record
- ☐ Minimal effect on mental acuity, in proper dosage
- ☐ Predictable patient response
- ☐ Is used concomitantly with primary medications, such as anticholinergics and cardiovascular drugs

Librium® 5mg, 10mg, 25mg capsules
chlordiazepoxide HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states. Efficacy beyond four months not established by systematic clinical studies. Periodic reassessment of therapy recommended.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Warn patients that mental and/or physical abilities required for tasks such as driving or operating machinery may be impaired, as may be mental alertness in children, and that concomitant use with alcohol or CNS depressants may have an additive effect. Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Usual Daily Dosage: Individualize for maximum beneficial effects. *Oral–Adults:* Mild and moderate anxiety and tension, 5 or 10 mg *t.i.d.* or *q.i.d.*; severe states, 20 or 25 mg *t.i.d.* or *q.i.d. Geriatric patients:* 5 mg *b.i.d.* to *q.i.d.* (See Precautions.)

Supplied: Librium® (chlordiazepoxide HCl) *Capsules*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10. Libritabs® (chlordiazepoxide) *Tablets*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500. With respect to clinical activity, capsules and tablets are indistinguishable.

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

Order Form: Paperback Edition

FELLOWSHIP IN CHILD PSYCHIATRY — STARTING July 1, 1979

The Division of Child Psychiatry offers a two-year, fully-accredited Fellowship in Child Psychiatry to qualified applicants who have completed an internship and two years of training in General Psychiatry. Salary range is $20,856 to $25,260.

The Fellowship offers a developmental psychophysiologic, psychodynamically oriented, active teaching program in all areas of child psychiatry with an opportunity for clinical and basic research. A distinguishing feature is integrated training in pediatric neurology, a multidisciplinary diagnostic clinic for learning and behavioral disorders, and liaison work with an outstanding pediatrics department.

Extensive individual supervision in family, group and behavioral therapy approaches as well as intensive psychoanalytically-oriented individual psychotherapy and play therapy are provided. Community child psychiatry experience is ample and includes consultation rotations with schools, adoption agencies, etc.

To apply for this exciting, rapidly-growing program, please contact:

Rita R. Rogers, M.D.
Chief, Division of Child Psychiatry
Harbor-UCLA Medical Center
1000 West Carson Street
Torrance, California 90509
(213) 533-3112 or 533-3175

PSYCHIATRIC RESIDENCY TRAINING PROGRAM

Immediate and July openings in fully accredited AMA approved 4 year psychiatric residency training program in association with; and with didactic instruction by SUNY Downstate Medical Center. Eclectic orientation with exposure to all schools of psychiatric thought. Openings are at PGY I, II and III levels.

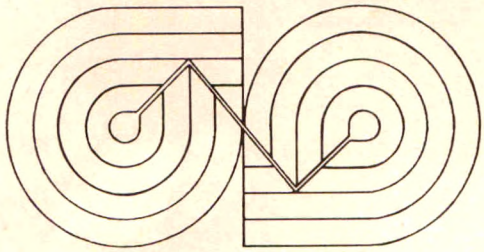
SENIOR PSYCHIATRIST NOVA SCOTIA, CANADA

The Nova Scotia Hospital invites applications for the position of Senior Psychiatrist. This is an excellent opportunity for a psychiatrist to direct a multi-disciplinary professional team.

Located in the Halifax-Dartmouth metropolitan area, this fully accredited hospital with a rapidly developing Community Mental Health Program and affiliated with Dalhousie University is the principle psychiatric facility for the Province.



Candidates must have Canadian Fellowship or equivalent qualifications. Assistance with licensure in the Province of Nova Scotia is provided. A limited private practice is officially approved for all full-time psychiatrists.

There is a liberal range of Civil Service benefits including four weeks annual vacation after five years, sick leave benefits, groups life insurance, relocation assistance, etc.

Salary up to $46,135. (under review for 1979)

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

PSYCHIATRY RESEARCH

An International Journal for Rapid Communications
providing researchers and clinicians with a unique opportunity for the rapid dissemination of important and novel ideas

Editors-in Chief:
MONTE S. BUCHSBAUM, Bethesda, MD, U.S.A.
FREDERICK K. GOODWIN, Bethesda, MD, U.S.A.

Mailing Address for Journal Matters: "Psychiatry Research" Box 34912, Bethesda MD, 20034, U.S.A.

Associate Editors: **J. Glowinski,** *Paris, France.* **R.M. Post,** *Bethesda, MD, U.S.A.* **H.M. van Praag,** *Utrecht, The Netherlands.* **O.J. Rafaelson,** *Copenhagen, Denmark.* **H.H. Strupp,** *Nashville, TN, U.S.A.,* and **P.H. Wender,** *Salt Lake City, UT, U.S.A.*

The ever-increasing expansion of knowledge and interest in the field of psychiatry has created an urgent need for a medium through which researchers and clinicians can communicate results and ideas quickly. Psychiatry Research aims to fulfill these needs.
Combining elegant computer typesetting technology with efficient administrative mechanisms, a skilled and decisive editorial board, and location of the editorial office in a major psychiatric research center, it will publish papers within three months of acceptance of manuscripts.

Aims and Scope.
The journal provides very rapid publication of short but complete research reports in the field of psychiatry. The scope of the journal encompasses (1) Biochemical, physiological, genetic, psychological and social determinants of human behavior; (2) assessment of human behavior and subjective state; (3) evaluation of somatic and nonsomatic psychiatric treatments. In addition, reports of clinically related basic studies in the fields of neuropharmacology, neurochemistry, electrophysiology, psychology, and genetics will be published. Significant methodological advances such as instrumentation, clinical scales, and assays directly applicable to psychiatric research will also be appropriate. Book reviews will be a regular feature. Brief reviews, theoretical contributions, and letters to the editor will be considere

5442 B

Tranxene® (CLORAZEPATE DIPOTASSIUM) 4306CB

CAPSULES,
SINGLE DOSE TABLETS
Brief Summary

ACTIONS — Pharmacologically, clorazepate dipotassium has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine. (See CLINICAL PHARMACOLOGY section.)

INDICATIONS — TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS — TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS — TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS — In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS — The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION

For the symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For the symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg. TRANXENE initially, followed by 30 to 60 mg. in divided doses; 2nd 24 hours, 45 to 90 mg. in divided doses; 3rd 24 hours, 22.5 to 45 mg. in divided doses; 4th day, 15 to 30 mg. in divided doses. Thereafter gradually reduce to 7.5 to 15 mg. daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS — If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE — Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE (clorazepate dipotassium) as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY — Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption — Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED — TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 30 (NDC 0074-3418-30), 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3418-11).

15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 30 (NDC 0074-2699-30) and 100 (NDC 0074-2699-13).

Awake on the job, yet anxiety controlled

Troublesome drowsiness uncommon. Tranxene lets you manage anxiety in most patients without problem sedation. Any initial drowsiness is usually transient. By avoiding excessive sedation, Tranxene helps you calm patients without compromising their capacities.*

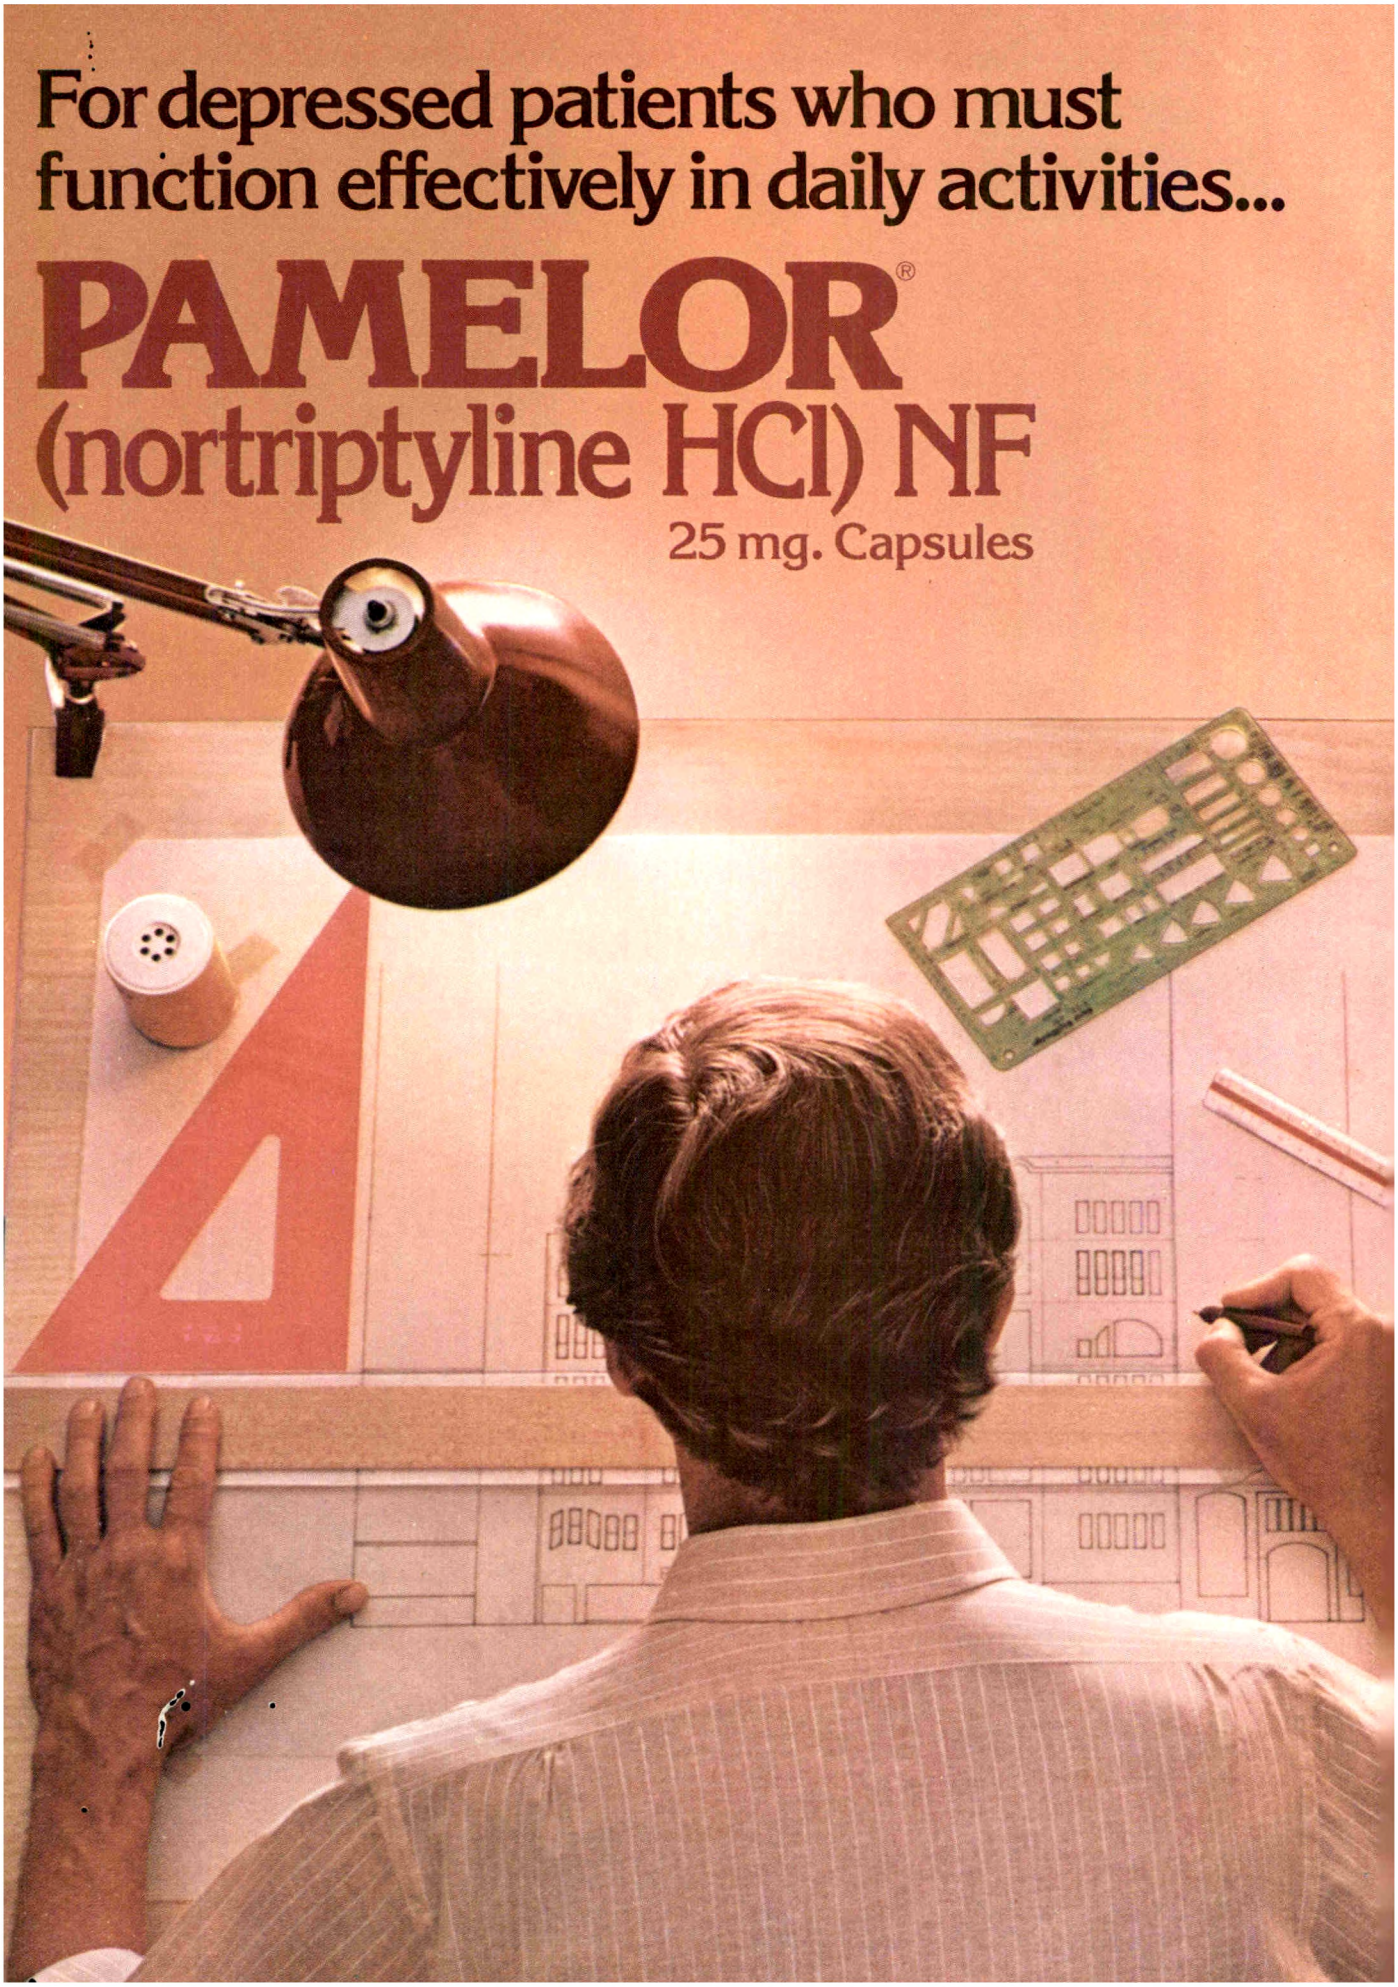
Depression and Alcoholism



OFFICIAL JOURNAL OF THE
AMERICAN PSYCHIATRIC ASSOCIATION

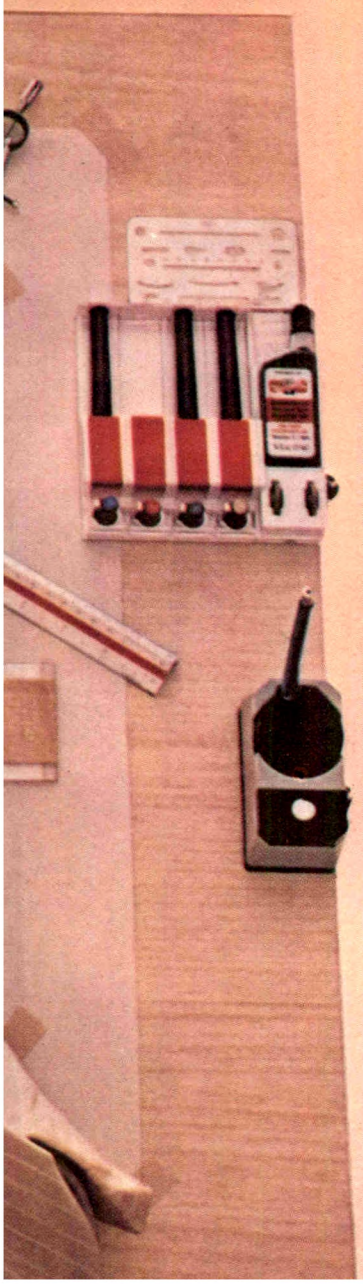
UNIVERSITY COLLEGE
LIBRARY

For depressed patients who must function effectively in daily activities...

PAMELOR®
(nortriptyline HCl) NF

25 mg. Capsules

Patients remain alert.



Most depressed patients must function effectively in their daily activities, on the job or at home. For these patients, PAMELOR capsules may be an appropriate therapeutic choice. PAMELOR relieves depression, yet rarely causes daytime drowsiness. As with all antidepressants, however, patients should be cautioned against driving or operating hazardous machinery.

Insomnia of depression begins to improve within a week.

PAMELOR capsules are effective for relieving insomnia, a cardinal symptom of depressive illness. Patients begin to sleep better within the first week of therapy. The full therapeutic effect of PAMELOR is usually observed by the second week.

PAMELOR therapy is well tolerated.

In 90 studies, a total of 818 patients were treated with PAMELOR capsules. Of the patients who improved completely or markedly, over half (54%) had no side effects. Those who experienced side effects most commonly complained of dry mouth.

Indications: For relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Hypersensitivity. Should not be given concomitantly with MAO inhibitors or within 2 weeks of the use of this drug since hyperpyretic crises, severe convulsions, and fatalities have occurred when similar tricyclic antidepressants were used in such combinations. Cross-sensitivity with other dibenzazepines is a possibility. Contraindicated during acute recovery period after myocardial infarction.

Warnings: Use with caution in patients with cardiovascular disease because of tendency to produce sinus tachycardia and prolong conduction time. Myocardial infarction, arrhythmia, and strokes have occurred. May block antihypertensive action of guanethidine and similar agents. Because of anticholinergic activity, use cautiously in patients with glaucoma or a history of urinary retention. Patients with a history of seizures should be followed closely because the drug is known to lower the convulsive threshold. Great care is required for hyperthyroid patients and those taking thyroid medication because of possible development of cardiac arrhythmia. Caution patients about possibility of impaired mental and/or physical ability to operate a motor vehicle or dangerous machinery. Response to alcoholic beverages may be exaggerated and may lead to suicidal attempts. Safe use during pregnancy, lactation, and women of childbearing potential has not been established and the drug should not be given unless clinical situation warrants potential risk. Not recommended for use in children.

Precautions: Psychotic symptoms may be exacerbated in schizophrenic patients. Increased anxiety and agitation may occur in overactive or agitated patients. Manic-depressive patients may experience shift to manic phase. Hostility may be aroused. Concomitant administration of reserpine may produce a "stimulating" effect. Watch for possible epileptiform seizures during treatment. Use cautiously with anticholinergic or sympathomimetic drugs. Concurrent electroconvulsive therapy may increase hazards associated with nortriptyline HCl. When possible, discontinue drug several days prior to surgery. Potentially suicidal patients require supervision and protective measures during therapy. Prescriptions should be limited to the least possible quantity. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: The pharmacologic similarities among the tricyclic antidepressant drugs require that each of the following reactions be considered when nortriptyline is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia, panic, nightmares; hypomania; exacerbation of psychosis.

Neurologic: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alteration in EEG patterns; tinnitus.

Anticholinergic: Dry mouth and rarely, associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with other tricyclic drugs.

Hematologic: Bone-marrow depression, including agranulocytosis; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black-tongue.

Endocrine: Gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness, fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though these are not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Dosage and Administration: *Usual adult dose*—25 mg. three or four times daily; dosage should begin at a low level and increase as required. As an alternate regimen, the total daily dosage may be given once-a-day. *Elderly and Adolescent*—30 to 50 mg. per day, in divided doses, or the total dosage may be given once-a-day. Doses above 100 mg. per day and use in children are not recommended. If a patient develops minor side effects, the dosage should be reduced. The drug should be discontinued promptly if adverse effects of a serious nature or allergic manifestations occur.

How Supplied: Capsules 10 mg. and 25 mg.; solution 10 mg./5 cc.

For more detailed information see full prescribing information.

ANNOUNCING PUBLICATION OF

THE CHRONIC MENTAL PATIENT

Report of a Conference held in January 1978
Edited by
John A. Talbott, M.D.

with contributions by James T. Barter, M.D., Paul R. Friedman, J.D., Raymond Glasscote, M.A., Trevor D. Glenn, M.D., Norman V. Lourie, M.S.W., W. Walter Menninger, M.D., Arthur T. Meyerson, M.D., Kenneth Minkoff, M.D., Samuel Muszynski, M.S.W., Lucy D. Ozarin, M.D., Gordon L. Paul, Ph.D., Ronald Peterson, Steven S. Sharfstein, M.D., Judith Clark Turner, Jane Bloom Yohalem, J.D.

This 277-page Report of the Conference, sponsored by APA and President Carter's Commission on Mental Health, identifies the chronic mental patient population, spells out where they are and what their needs and rights are. It specifies what programs work and what programs do not work in meeting the needs of these patients. It elaborates on the obstacles to implementing effective programs and the economic issues involved. It delineates the pros and cons of case management and specifies responsibility for coordinating, implementing, and monitoring services to chronic mental patients.

Finally, it proposes a *Call to Action* which opens with this statement: "There is no more urgent concern than the needs of the chronic mentally ill who suffer from severe, persistent, or recurrent mental illnesses with residual social and vocational disabilities. As a result of the deinstitutionalization programs of the past decade and the continuing growth of high risk populations that generate chronically ill, the problems associated with the care of these patients constitute a national crisis."

Since the Conference, the APA Assembly and the Board of Trustees have both approved the "Call to Action" which calls upon the APA to take the lead in undertaking programs to elevate the prestige and value of work with chronic mentally ill patients.

It follows that all APA members should be thoroughly versed in the current problems of this chronic patient population. This is best accomplished by reading this Conference Report now available from APA Publications Services at $11.00 a copy.

THE AMERICAN JOURNAL OF PSYCHIATRY

CONTENTS Vol. 136, No. 4B April 1979

SPECIAL ISSUE: Depression and Alcoholism

497 Editorial: Diverse Research Strategies for Depression and Alcoholism
Morris A. Lipton

502 Life Events, Coping, Stress, and Depressive Symptomatology
George J. Warheit

508 Life Events at the Onset of Bipolar Affective Illness
David L. Dunner, Vijayalakshmy Patrick, and Ronald R. Fieve

511 Childhood Depression: Interpersonal Interactions and Depressive Phenomena
Irving Philips

516 The Psychopathology of Suicide: A Clinical Model Approach
Jerome A. Motto

521 Depression Simulating Organic Brain Disease
Jesse O. Cavenar, Jr., Allan A. Maltbie, and Linda Austin

524 Depression in the Wives of Nuclear Submarine Personnel
Karen Beckman, Anthony J. Marsella, and Ruth Finney

526 Depression in Viet Nam Veterans and Civilian Controls
John E. Helzer, Lee N. Robins, Eric Wish, and Michi Hesselbrock

530 Depressed Mood and Subsequent Physical Illness
Evelyn L. Goldberg, George W. Comstock, and Robijn K. Hornstra

535 Depression: New Evidence in Support of Biological Differentiation
Paul E. Garfinkel, Jerry J. Warsh, and Harvey C. Stancer

540 Physical Activity and Plasma Cyclic Adenosine Monophosphate Levels in Manic-Depressive Patients and Healthy Adults
Eleftherios Lykouras, Evangelos Garelis, Eleftheria Varsou, and Costas N. Stefanis

543 The 24-Hour Dexamethasone Suppression Test in a Clinical Setting: Relationship to Diagnosis, Symptoms, and Response to Treatment
Walter Armin Brown, Robert Johnston, and Demmie Mayfield

548 Facial Muscle Electromyography in Depressed and Nondepressed Hospitalized Subjects: A Partial Replication
Donald Oliveau and Ragon Willmuth

551 Diagnosis and Lithium Treatment of Affective Disorder in the Retarded: Five Case Studies
Timothy M. Rivinus and Jerold S. Harmatz

555 The Efficacy of Drugs and Psychotherapy in the Treatment of Acute Depressive Episodes
Myrna M. Weissman, Brigitte A. Prusoff, Alberto DiMascio, Carlos Neu, Mahesh Goklaney, and Gerald L. Klerman

559 Depression Treated with Imipramine and ECT: The DeCarolis Study Reconsidered
David Avery and Aldo Lubrano

563 Lithium Maintenance: Factors Affecting Outcome
James H. Kocsis and Peter E. Stokes

567 The Delineation of an MMPI Symptom Pattern Unique to Lithium Responders
Fred A. Steinberg

570 Treatment of Tardive Dyskinesia and Mania with RBC Lithium Determinations
Larry Ereshefsky, Terry N. Rubin, and Stephen Friedman

574 Exacerbation of Psychosis by Tricyclic Antidepressants in Delusional Depression
J. Craig Nelson, Malcolm B. Bowers, Jr., and Donald R. Sweeney

577 A Possible Cardiovascular Effect of Lithium
Robert H. Belmaker, Rachel Lehrer, Richard P. Ebstein, Haya Lettik, and Sol Kugelmass

580 The Quantitative Measurement of Depression and Anxiety in Male Alcoholics
John E. Hamm, Leslie F. Major, and Gerald L. Brown

583 Bipolar Illness: Factors in Drinking Behavior
David L. Dunner, Bruce M. Hensel, and Ronald R. Fieve

586 Are All Recently Detoxified Alcoholics Depressed?
Martin H. Keeler, C. Inga Taylor, and William C. Miller

589 Family Rituals and the Recurrence of Alcoholism Over Generations
Steven J. Wolin, Linda A. Bennett, and Denise L. Noonan

594 Short-Term Spatial Memory Deficits in Men Arrested for Driving While Intoxicated
Eric W. Fine and Robert A. Steer

598 Computerized Transaxial Tomographic and Neuropsychological Evaluations in Chronic Alcoholics and Heroin Abusers
Shirley Y. Hill and Michael A. Mikhael

603 Craving for Alcohol in Sober Alcoholics
Roy J. Mathew, James L. Claghorn, and John Largen

607 Drug Abuse Among Alcoholic Women
Marc A. Schuckit and Elizabeth R. Morrissey

611 Psychiatric Problems in Women Admitted to an Alcoholic Detoxification Center
Marc A. Schuckit and Elizabeth R. Morrissey

618 Interpersonal Attractiveness and Clinical Decisions in Alcoholism Treatment
Michael R. O'Leary, Dennis M. Donovan, Edmund F. Chaney, and Diane E. O'Leary

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions, and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot

studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality, and authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications (no précis is used in the Clinical and Research Reports section). The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material; a complete review of the literature is rarely desirable. *Accuracy of citation is the author's responsibility.* References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do *not* arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list the name of the journal must be included.

Type references in the style shown below and on the next page, double-spaced *throughout* (not just a line between

references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2-6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

  By Loren R. Mosher and Samuel J. Keith

Lithane® 300 mg Tablets
(lithium carbonate)

WARNING

Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

DESCRIPTION: Lithium carbonate is a white, light, alkaline powder with molecular formula Li_2CO_3 and molecular weight 73.89. Lithium is an element of the alkali-metal group with atomic number 3, atomic weight 6.94, and an emission line at 671 mμ on the flame photometer.

ACTIONS: Preclinical studies have shown that lithium alters sodium transport in nerve and muscle cells and effects a shift toward intraneuronal metabolism of catecholamines, but the specific biochemical mechanism of lithium action in mania is unknown.

INDICATIONS: Lithium carbonate is indicated in the treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in those manic-depressive patients with a history of mania.

Typical symptoms of mania include pressure of speech, motor hyperactivity, reduced need for sleep, flight of ideas, grandiosity, elation, poor judgment, aggressiveness, and possibly hostility. When given to a patient experiencing a manic episode, lithium may produce a normalization of symptomatology within 1 to 3 weeks.

WARNINGS: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, or sodium depletion, and to patients receiving diuretics, since the risk of lithium toxicity is very high in such patients. If the psychiatric indication is life-threatening, and if such a patient fails to respond to other measures, lithium treatment may be undertaken with extreme caution, including daily serum lithium determinations and adjustment to the usually low doses ordinarily tolerated by these individuals. In such instances, hospitalization is a necessity.

Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels (see DOSAGE AND ADMINISTRATION).

Outpatients and their families should be warned that the patient must discontinue lithium carbonate therapy and contact his physician if such clinical signs of lithium toxicity as diarrhea, vomiting, tremor, mild ataxia, drowsiness, or muscular weakness occur.

Usage in Pregnancy: Adverse effects on nidation in rats, embryo viability in mice and metabolism *in vitro* of rat testis and human spermatozoa have been attributed to lithium, as have teratogenicity in submammalian species and cleft palates in mice. Studies in rats, rabbits, and monkeys have shown no evidence of lithium-induced teratology.

There are lithium birth registries in the United States and elsewhere: however there is at the present time insufficient data to determine the effects of lithium carbonate on human fetuses. Therefore, at this point, lithium should not be used in pregnancy, especially the first trimester, unless in the opinion of the physician; the potential benefits outweigh the possible hazards.

Usage in Children: Since information regarding the safety and effectiveness of lithium carbonate in children under 12 years of age is not available, its use in such patients is not recommended at this time.

COMBINED USE OF HALOPERIDOL AND LITHIUM: An encephalopathic syndrome (characterized by weakness, lethargy, fever, tremulousness and confusion, extrapyramidal symptoms, leucocytosis, elevated serum enzymes, BUN and FBS) followed by irreversible brain damage has occurred in a few patients treated with lithium plus haloperidol. A causal relationship between these events and the concomitant administration of lithium and haloperidol has not been established; however, patients receiving such combined therapy should be monitored closely for early evidence of neurological toxicity and treatment discontinued promptly if such signs appear.

PRECAUTIONS: The ability to tolerate lithium is greater during the acute manic phase and decreases when manic symptoms subside (see DOSAGE AND ADMINISTRATION).

The distribution space of lithium approximates that of total body water. Lithium is primarily excreted in urine with insignificant excretion in feces. Renal excretion of lithium is proportional to its plasma concentration. The half-elimination time of lithium is approximately 24 hours. Lithium decreases sodium reabsorption by the renal tubules which could lead to sodium depletion. Therefore, it is essential for the patient to maintain a normal diet, including salt, and an adequate fluid intake (2500–3000 ml) at least during the initial stabilization period. Decreased tolerance to lithium has been reported to ensue from protracted sweating or diarrhea and, if such occur, supplemental fluid and salt should be administered.

In addition to sweating and diarrhea, concomitant infection with elevated temperatures may also necessitate a temporary reduction or cessation of medication.

Untoward reactions to simultaneous use of lithium and other psychoactive drugs have not been reported. However, the possibility of adverse interaction with other anti-psychotic medications remains.

ADVERSE REACTIONS: Adverse reactions are seldom encountered at serum lithium levels below 1.5 mEq/L, except in the occasional patient sensitive to lithium. Mild to moderate toxic reactions may occur at levels from 1.5–2.5 mEq/L, and moderate to severe reactions may be seen at levels from 2.0–2.5 mEq/L, depending upon individual response to the drug.

Fine hand tremor, polyuria, and mild thirst may occur during initial therapy for the acute manic phase, and may persist throughout treatment. Transient and mild nausea and general discomfort may also appear during the first few days of lithium administration.

These side effects are an inconvenience rather than a disabling condition, and usually subside with continued treatment or a temporary reduction or cessation of dosage. If persistent, a cessation of dosage is indicated.

Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of lithium intoxication, and can occur at lithium levels below 2.0 mEq/L. At higher levels, giddiness, ataxia, blurred vision, tinnitus, and a large output of dilute urine may be seen. Serum lithium levels above 3.0 mEq/L may produce a complex clinical picture involving multiple organs and organ systems. Serum lithium levels should not be permitted to exceed 2.0 mEq/L during the acute treatment phase.

The following toxic reactions have been reported and appear to be related to serum lithium levels:

Neuromuscular: Tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflexes.

Central Nervous System: Blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma.

Cardiovascular: Cardiac arrhythmia, hypotension, peripheral circulatory collapse.

Gastrointestinal: Anorexia, nausea, vomiting, diarrhea.

Genitourinary: Albuminuria, oliguria, polyuria, glycosuria.

Dermatologic: Drying and thinning of hair, anesthesia of skin, chronic folliculitis, xerosis cutis.

Autonomic Nervous System: Blurred vision, dry mouth.

Miscellaneous: Fatigue, lethargy, tendency to sleep, dehydration, weight loss, transient scotomata.

Thyroid Abnormalities: Euthyroid goiter and/or hypothyroidism (including myxedema) accompanied by lower T_3 and T_4. ^{131}I uptake may be elevated. Underlying thyroid disorders do not constitute a contraindication to lithium treatment; careful monitoring of thyroid function during lithium stabilization and maintenance allows for correction of changing thyroid parameters, if any. They can be treated by prescribing thyroid in these cases.

EEG Changes: Diffuse slowing, widening of frequency spectrum, potentiation and disorganization of background rhythm.

EKG Changes: Reversible flattening, isoelectricity or inversion of T-waves.

Miscellaneous Reactions Unrelated to Dosage: Transient electroencephalographic and electrocardiographic changes, leucocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, and thirst or polyuria, sometimes resembling diabetes insipidus. A single report has been received of the development of painful discoloration of fingers and toes and coldness of the extremities within one day of the starting of treatment of lithium. The mechanism through which these symptoms (resembling Raynaud's syndrome) developed is not known. Recovery followed discontinuance.

DOSAGE AND ADMINISTRATION: Acute Mania: Optimal patient response to lithium carbonate usually can be established and maintained with 600 mg t.i.d. Such doses will normally produce an effective serum lithium level ranging between 1.0 and 1.5 mEq/L. Dosage must be individualized according to serum levels and clinical response. Regular monitoring of the patient's clinical state and of serum lithium levels is necessary. Serum levels should be determined twice per week during the acute phase, and until the serum level and clinical condition of the patient have been stabilized.

Long-Term Control: The desirable lithium levels are 0.6 to 1.2 mEq/L. Dosage will vary from one individual to another, but usually 300 mg t.i.d. or q.i.d. will maintain this level. Serum lithium levels in uncomplicated cases receiving maintenance therapy during remission should be monitored at least every two months.

Patients abnormally sensitive to lithium may exhibit toxic signs at serum levels of 1.0 to 1.5 mEq/L. Elderly patients often respond to reduced dosage, and may exhibit signs of toxicity at serum levels ordinarily tolerated by other patients.

NB: Blood samples for serum lithium determinations are drawn 8–12 hours after the previous dose when lithium concentrations are relatively stable. Total reliance must not be placed on serum levels alone. Accurate patient evaluation requires both clinical and laboratory analysis.

OVERDOSAGE: The toxic levels for lithium are close to the therapeutic levels. It is therefore important that patients and their families be cautioned to watch for early toxic symptoms and to discontinue the drug and inform the physician should they occur. Toxic symptoms are listed in detail under ADVERSE REACTIONS.

Treatment: No specific antidote for lithium poisoning is known. Early symptoms of lithium toxicity can usually be treated by reduction or cessation of dosage of the drug and resumption of the treatment at a lower dose after 24 to 48 hours. In severe cases of lithium poisoning, the first and foremost goal of treatment consists of elimination of this ion from the organism.

Treatment is essentially the same as that used in barbiturate poisoning: 1) lavage, 2) correction of fluid and electrolyte imbalance and 3) regulation of kidney functioning. Urea, mannitol, and aminophylline all produce significant increases in lithium excretion. Infection prophylaxis, regular chest X-rays, and preservation of adequate respiration are essential.

HOW SUPPLIED: Lithane (lithium carbonate) is available as scored tablets containing 300 mg of lithium carbonate in bottles of 100 and 1000.

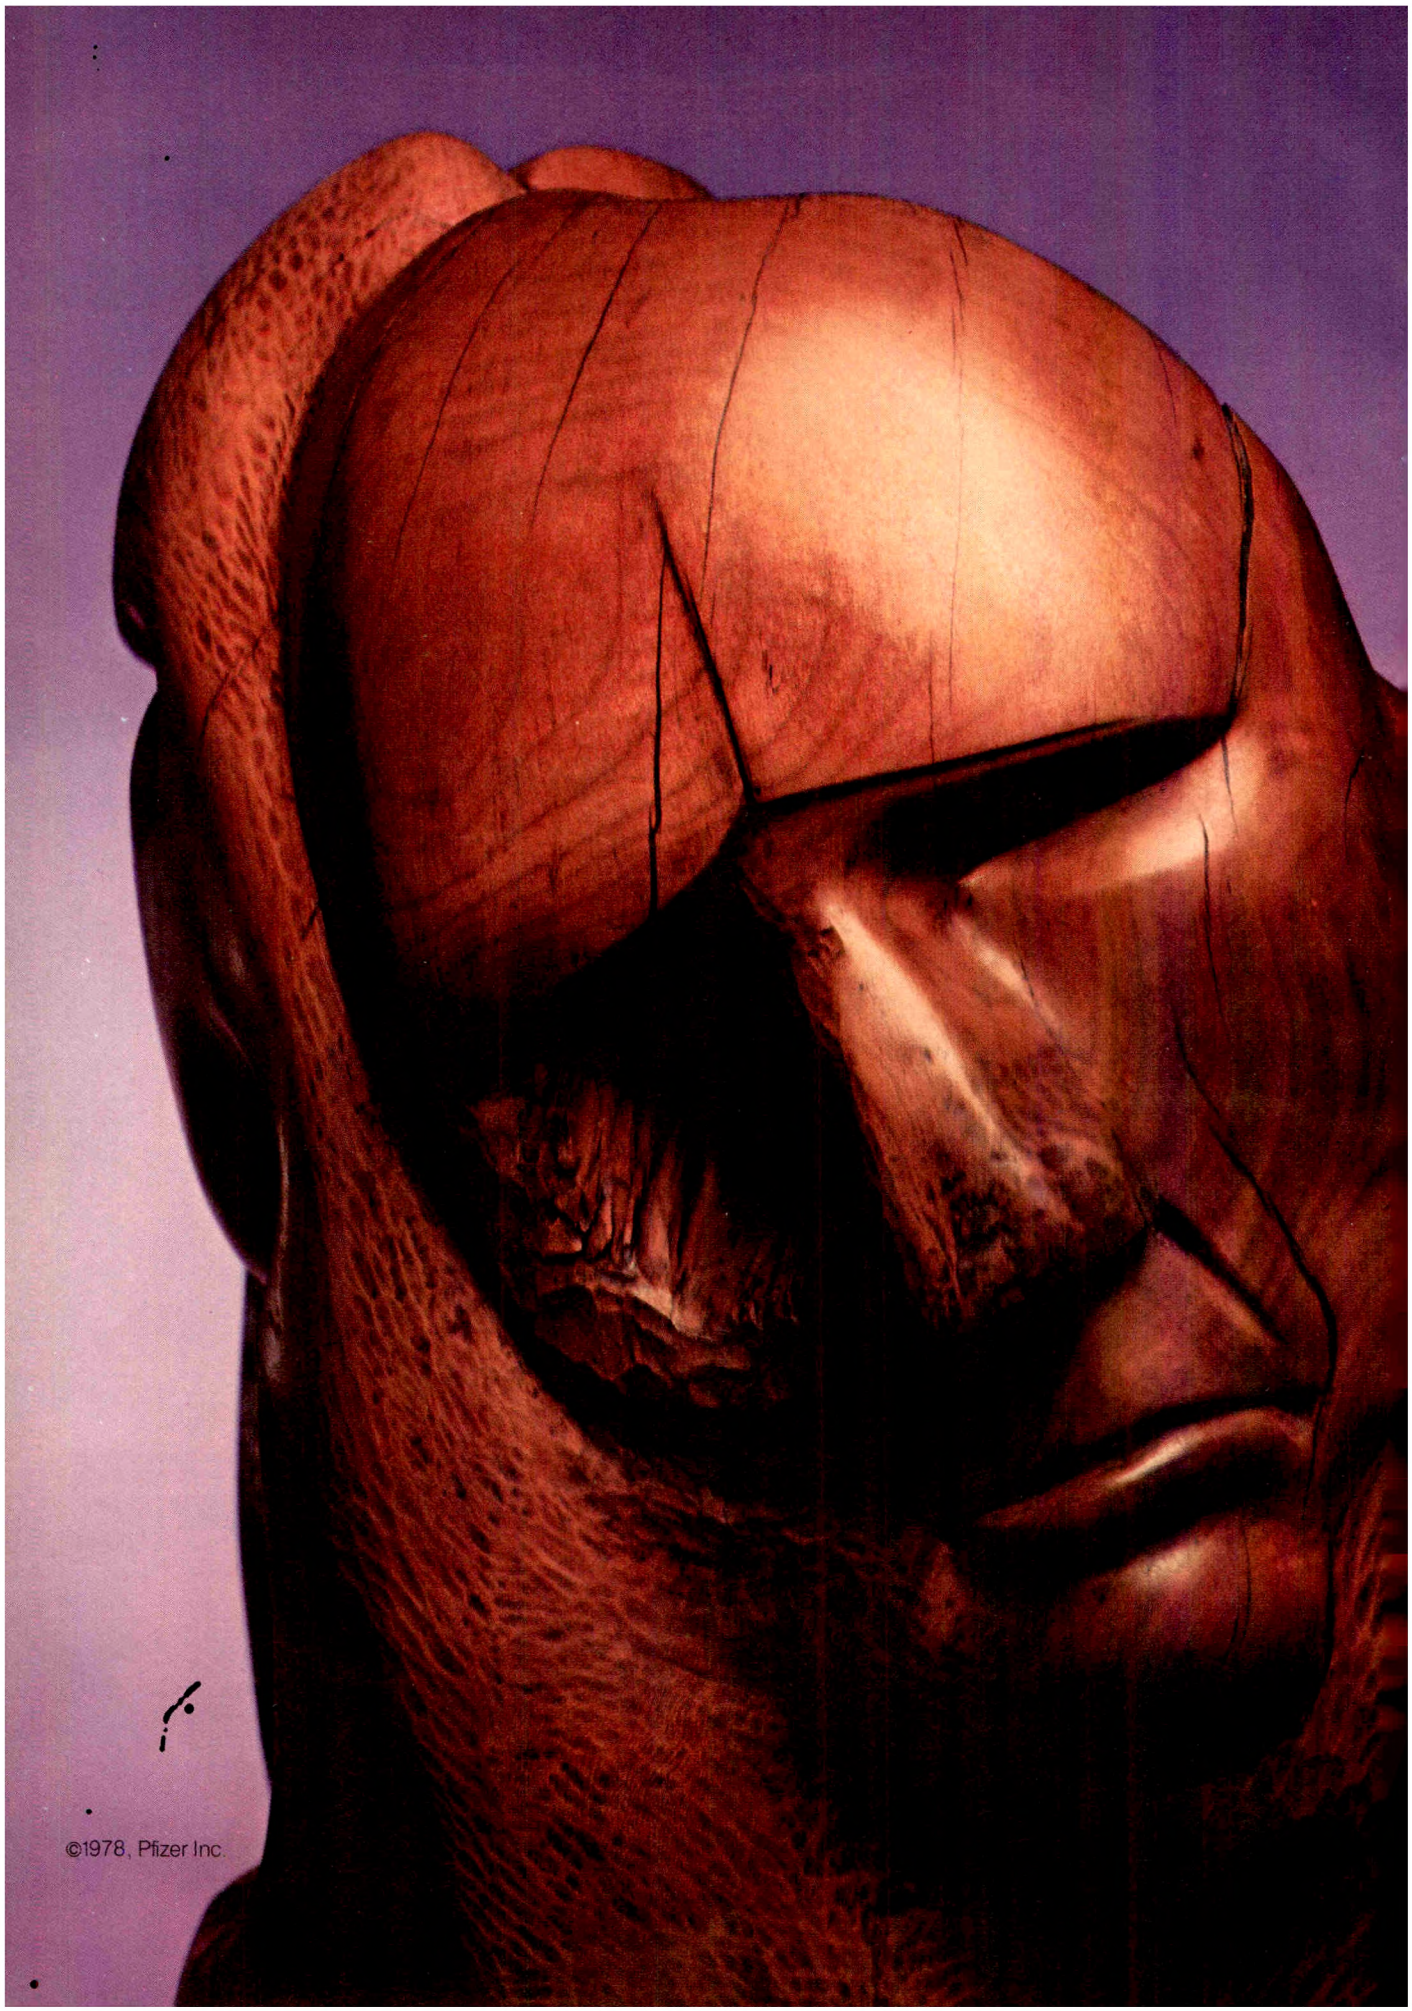
© 1978 DOME DIVISION, MILES LABORATORIES, INC. ALL RIGHTS RESERVED

George Frederick Handel
(1685-1759), known for his swings from depression to mania, composed his majestic *Messiah* oratorio in only six weeks. If he were living today, lithium would probably control his symptoms.

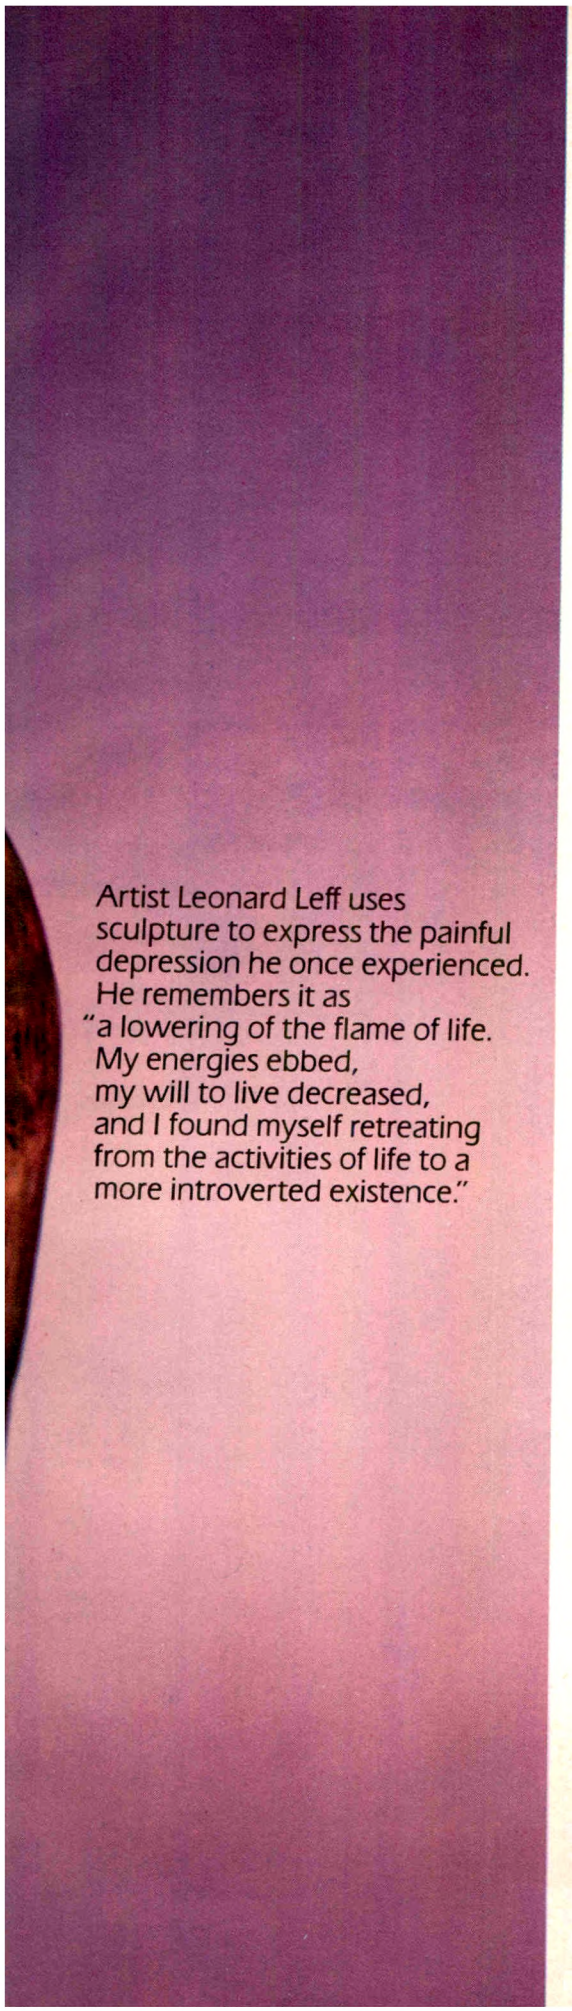
Now available from Dome:

To help you bring modern therapy to a classic syndrome...

Lithane® 300 mg Tablets
(lithium carbonate)



A basic element provides control of the manic phase of manic-depressive psychosis in responsive patients.



May we suggest that you see your Dome representative for the EMP (Empathic) COMMUNICATIONS program—a professional service designed to help your patients as well as their families and others in close contact with them.

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severit starting daily dose of 75 mg is recommended. Dosage may subsequently be increase decreased at appropriate intervals and according to individual response. The usual optim dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increas 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceedir dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying orga disease, lower doses may suffice. Some of these patients have been controlled on doses as as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a- dosage schedule. If the once-a-day schedule is employed the maximum recommended dos 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intended maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant ef may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ile hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggres supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautior prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absor The use of activated charcoal has been recommended, as has been continuous gastric lav with saline for 24 hours or more. An adequate airway should be established in comatose pati and assisted ventilation used if necessary. EKG monitoring may be required for several d since relapse after apparent recovery has been reported. Arrhythmias should be treated with appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow ir venous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmir rapidly metabolized, the dosage should be repeated as required. Convulsions may respor standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory dep sion. Dialysis and forced diuresis generally are not of value in the management of overdos due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibr at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 1 doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prur pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a numb carbonated beverages. For those patients requiring antidepressant therapy who ar methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be m together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not grape juice. Preparation and storage of bulk dilutions is not recommended.

A PRIVATE PSYCHIATRIC HOSPITAL

. . . for the diagnosis and treatment of all types of psychiatric disorders including alcohol and drug dependence – over ninety years continuous experience. A high ratio of psychiatrists to patients enables our staff to individualize treatment. All types of modern therapy are available through the skills of a modern, professional psychiatric team.

The Sanitarium is set in the midst of 55 acres of wooded parkland in the City of Guelph, which is located 50 miles south-west of Toronto, a 50 minute drive from Toronto International Airport.

All of the buildings and units have been modernized and are well planned and therapeutic in their design. The facilities provide excellent recreational areas. There is a modern Physiotherapy Department with a large whirlpool, active Horticultural Therapy Program and a large activity therapy program.

The semi-private rate is $85.90 per day for active treatment units and $79.90 per day for long-term care. The only additional charges are for medical and psychiatric services in accordance with the Ontario Medical Association fee schedule. Insurance benefits applicable depend on the nature of the illness and on the terms of the insurance policy.

For further information, write or telephone Mrs. Marion Glazier, Director of Admissions at The Homewood Sanitarium, 150 Delhi St., Guelph, Ont. N1E 6K9 Phone 1-519-824-1010.

breaking
through

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL" 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked agitation with depression

dual-action® **Triavil**

containing perphenazine and amitriptyline HCl

MSD
MERCK SHARP & DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

Suicide:

Theory and Clinical Aspects

Edited by Leon D. Hankoff, MD, SUNY at Stony Brook School of Medicine, and Bernice Einsidler, MS, New York Medical College

Twelve out of every one thousand deaths in the U.S. are suicides, ranking self-destruction among the top ten causes of death in this country. Psychiatrist Leon D. Hankoff places suicide within the scientific frameworks of public health and medicine in this penetrating new volume, with particular emphasis on prevention and treatment. He covers succinctly the historic and cultural issues essential to an understanding of suicidal behaviors, as well as the pertinent biological and psychological aspects. The heart of the book deals with effective therapeutic approaches for nine high-risk subgroups including the aged, alcoholics, prisoners, hospital patients, and others. The theme is integration of medical and nonmedical prevention strategies and the correlation of background findings to specific action-oriented programs.

1979 400 pages, illustrated $32.50

"A particularly timely book... Physicians will find much to help them do more good than harm in their efforts to allieviate the emotional ills brought on by this turbulent, stressful society."

—Robert B. Greenblatt, MD

Mind-Influencing Drugs

Effective Management of Patients with Emotional Illness

Edited by Martin Goldberg, MD, Institute of the Pennsylvania Hospital, Philadelphia, and Gerald Egelston, New York

Includes differential diagnosis of anxiety and depression, drug interactions and other considerations for total patient care. Emphasis is on treatment within the community, mainly by pharmacologic agents whose significant characteristics are described in detail.

1978 405 pages, illustrated $19.50

Clinical Psychopharmacology

Edited by Jerrold G. Bernstein, MD, Human Resource Institute of Boston and Harvard Medical School

A practical reference volume, this is the combined work of a number of eminent authorities in the field of psychopharmacology. It is designed as an introduction to the biologic and chemical aspects of psychiatric disorder for the purpose of recognizing, diagnosing, and treating its various forms. Pharmacotherapy and psychotherapy are correlated throughout as complementary forms of treatment.

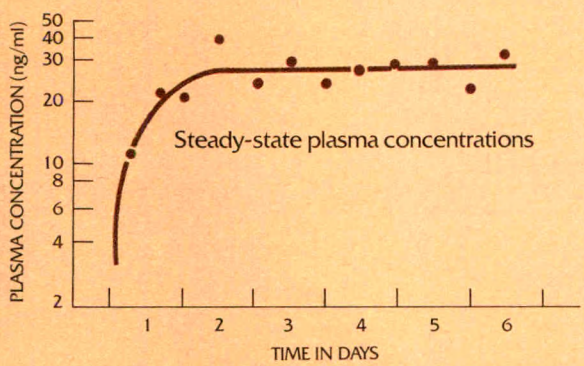
How to tell ATIVAN from other benzodiazepines.

Ativan is an effective, well-tolerated antianxiety agent. So are other benzodiazepines. But here are three ways Ativan stands out pharmacokinetically.*

1. Uncomplicated metabolic profile.

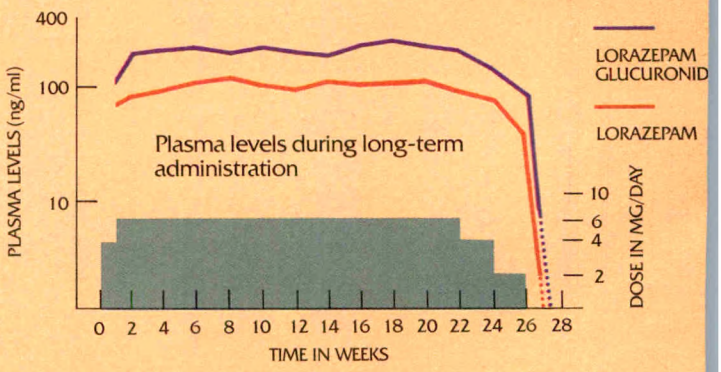
In contrast to most other benzodiazepines, the metabolic pathway of Ativan is straightforward. Ativan is active as given. Just one step from an active compound to an inactive one.

2. Steady-state levels achieved rapidly.



Most benzodiazepines take at least 7 to 10 days to reach steady-state serum levels. With Ativan, that equilibrium is reached in 2 to 3 days. A factor that can be important when you modify dosage schedules to meet individual needs.

3. No accumulation of multiple metabolites.

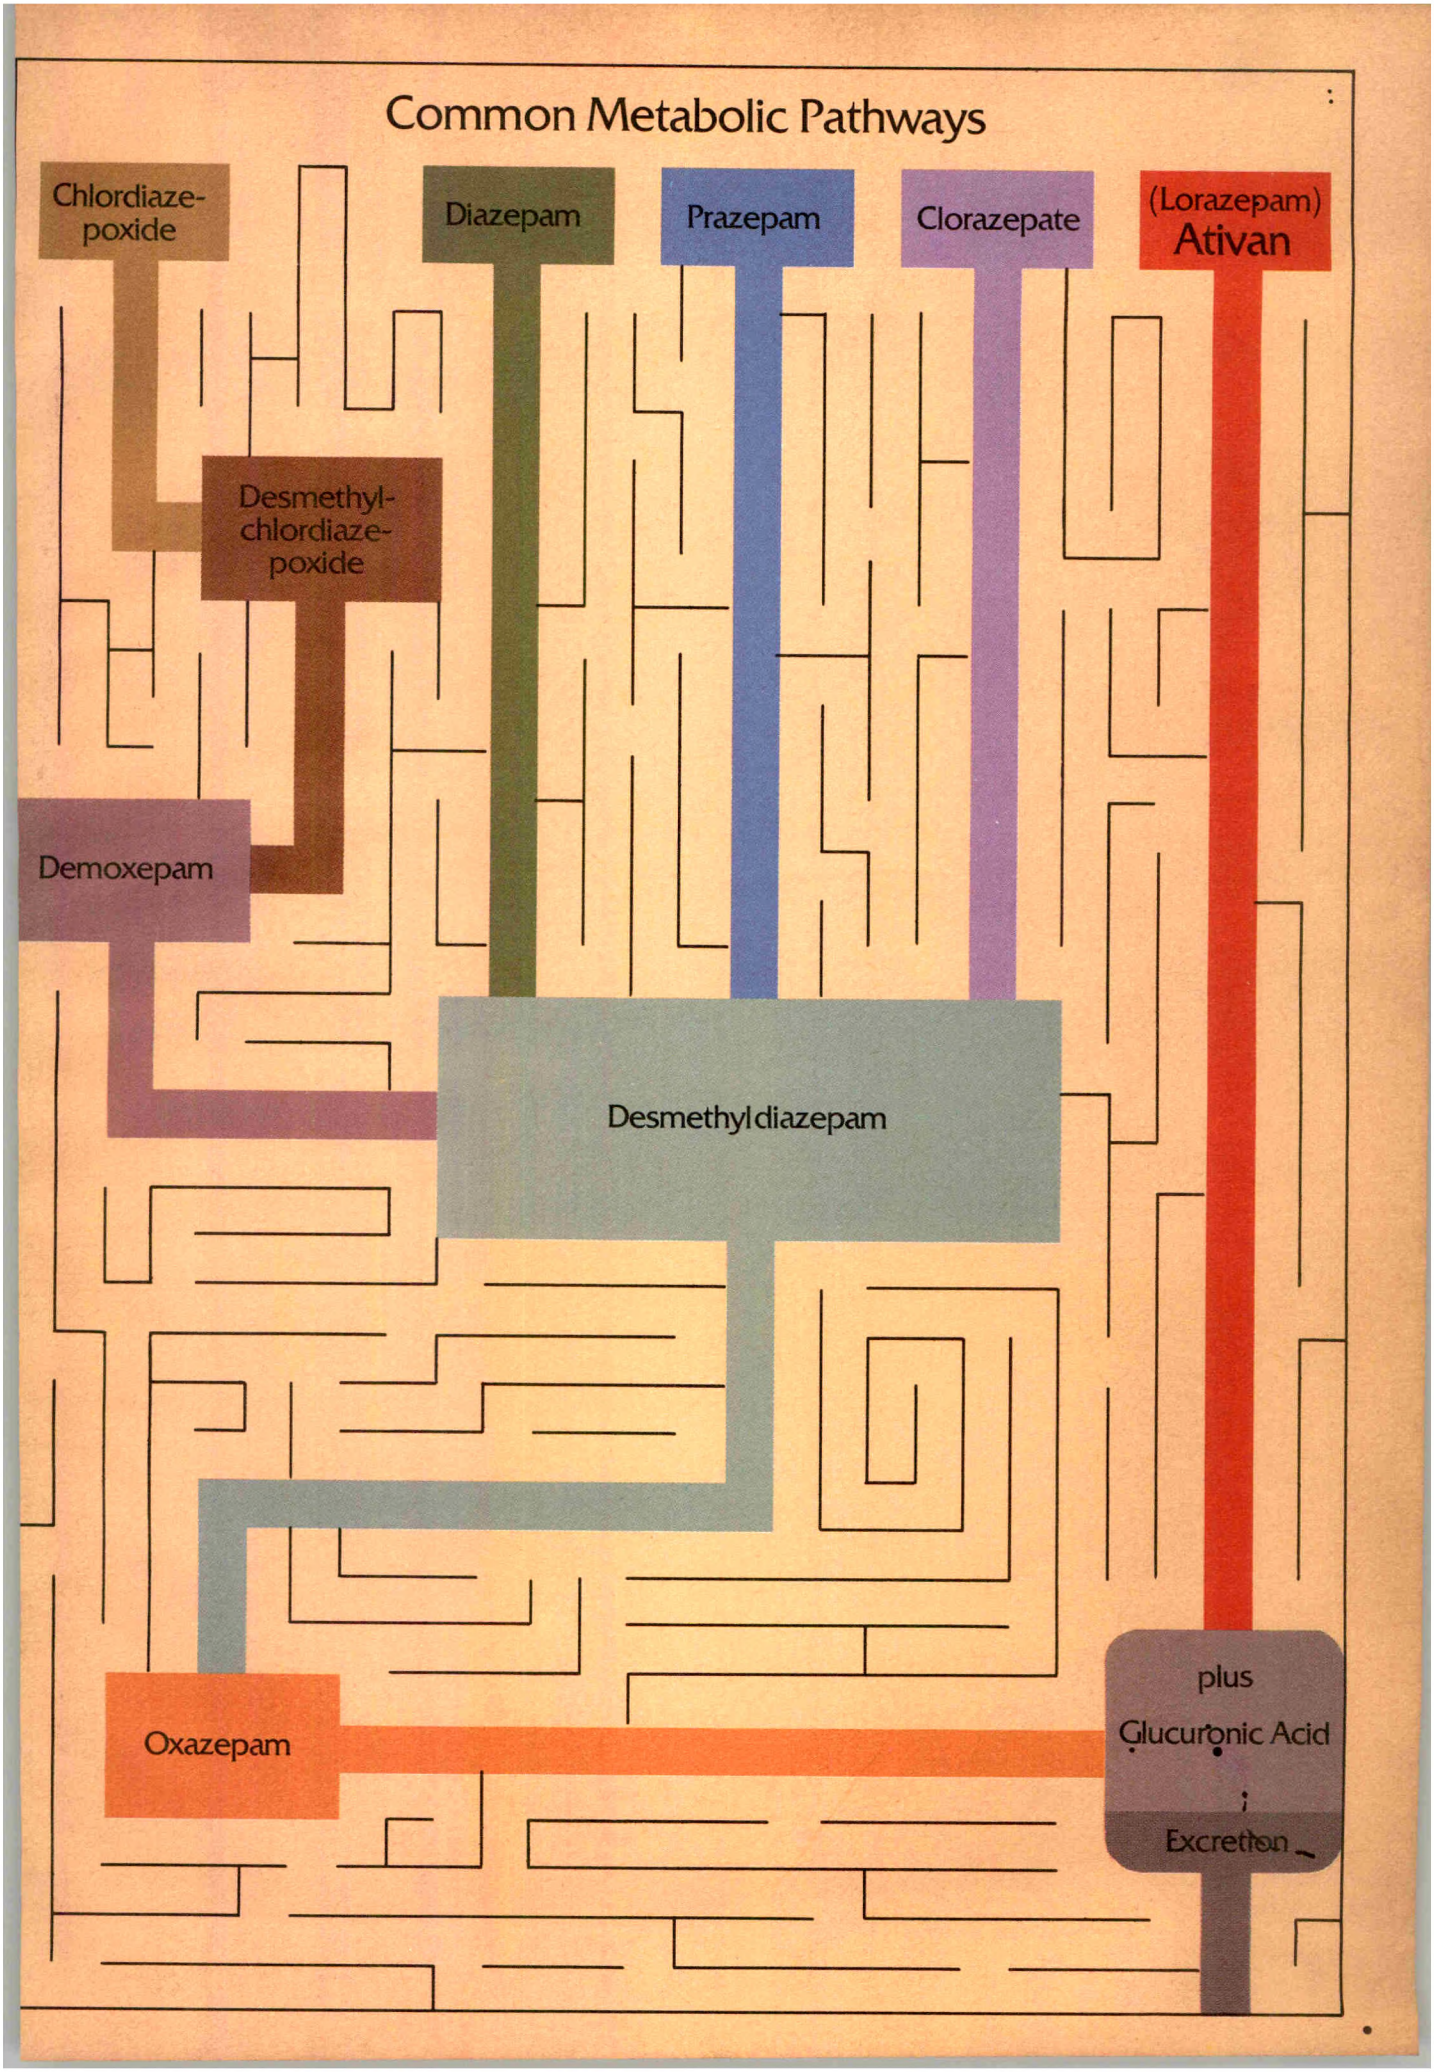


Because Ativan has no active metabolites to be eliminated at varying rates, steady-state levels are achieved predictably and smoothly. Six-month studies show no evidence of drug-accumulation above steady-state levels even at maximum daily dosages.

*The pharmacokinetic profile of a drug cannot, at present, be directly related to its therapeutic effectiveness.

Please refer to page after next for a summary of prescribing information.

Concentrations of lorazepam on repeated-dose regimen (single 1-mg. tablets given at 9 a.m., 3 p.m. and 9 p.m. daily for 6 days). A steady state is achieved after the second day, and is maintained thereafter.



Lorazepam and lorazepam glucuronide plasma levels in ng/ml during chronic oral administration of the drug over a period of six months. Each point represents the mean of 8 subjects. The daily maintenance dose in milligrams per subject is given at weekly intervals.

prescribing information

Contraindications: Ativan is contraindicated in patients with known sensitivity to the benzodiazepines or with acute narrow-angle glaucoma.

Warnings: Ativan is not recommended for use in patients with a primary depressive disorder or psychosis. As with all patients on CNS-acting drugs, patients receiving lorazepam should be warned not to operate dangerous machinery or motor vehicles and that their tolerance for alcohol and other CNS depressants will be diminished.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions: In patients with depression accompanying anxiety, a possibility for suicide should be borne in mind.

For elderly or debilitated patients, the initial daily dosage should not exceed 2 mg in order to avoid oversedation.

Ativan dosage should be terminated gradually since abrupt withdrawal of any antianxiety agent may result in symptoms similar to those for which patients are being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

The usual precautions for treating patients with impaired renal or hepatic function should be observed.

In patients where gastrointestinal or cardiovascular disorders coexist with anxiety, it should be noted that lorazepam has not been shown to be of significant benefit in treating the gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than one year at 6 mg/kg/day. The no-effect dose was 1.25 mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10 mg per day). The effect was reversible only when the treatment was withdrawn within two months of first observation of the phenomenon. The clinical significance of this is unknown. However, use of lorazepam for prolonged periods and in geriatric patients requires caution, and there should be frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness of Ativan in children of less than 12 years have not been established.

Essential Laboratory Tests: Some patients on Ativan have developed leukopenia and some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended for patients on long-term therapy.

Clinically Significant Drug Interactions: The benzodiazepines including Ativan produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

Carcinogenesis and Mutagenesis: No evidence of carcinogenic potential emerged in rats during an 18-month study with Ativan. No studies regarding mutagenesis have been performed.

Pregnancy: Reproductive studies in animals were performed in mice, rats, and two strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all of these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At doses of 40 mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses.

The clinical significance of the above findings is not known. However, an increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Because the use of these drugs is rarely a matter of urgency, the use of lorazepam during this period should almost always be avoided. The possibility that a woman of child-bearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant, they should communicate with their physician about the desirability of discontinuing the drug.

In humans, blood levels obtained from umbilical cord blood indicate placental transfer of lorazepam and lorazepam glucuronide.

Nursing Mothers: It is not known whether oral lorazepam is excreted in human milk like the other benzodiazepine tranquilizers. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

Adverse Reactions: Adverse reactions, if they occur, are usually observed at the beginning of therapy and generally disappear on continued medication or upon decreasing the dose. In a sample of about 3,500 anxious patients, the most frequent adverse reaction to Ativan is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent adverse reactions are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, together with various gastrointestinal symptoms and autonomic manifestations. The incidence of sedation and unsteadiness increased with age.

Small decreases in blood pressure have been noted but are not clinically significant, probably being related to the relief of anxiety produced by Ativan.

Overdosage: In the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

Manifestations of Ativan overdosage include somnolence, confusion and coma. Induced vomiting and/or gastric lavage should be undertaken followed by general supportive care, monitoring of vital signs and close observation of the patient. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection, U.S.P. Caffeine and Sodium Benzoate Injection, U.S.P. may be used to counteract CNS depressant effects. The usefulness of dialysis has not been determined.

Dosage and Administration: Ativan is administered orally. For optimal results, dose, frequency of administration and duration of therapy should be individualized according to patient response. To facilitate this, scored 1.0 and 2.0 mg tablets are available.

The usual range is 2 to 6 mg/day given in divided doses, the largest dose being taken before bedtime, but the daily dosage may vary from 1 to 10 mg/day. For anxiety, most patients require an initial dose of 2 to 3 mg/day given b.i.d. or t.i.d.

For insomnia due to anxiety or transient situational stress, a single daily dose of 2 to 4 mg may be given, usually at bedtime.

For elderly or debilitated patients, an initial dosage of 1 to 2 mg/day in divided doses is recommended, to be adjusted as needed and tolerated.

The dosage of Ativan should be increased gradually when needed to help avoid adverse effects. When higher dosage is indicated, the evening dose should be increased before the daytime doses.

How Supplied: Ativan (lorazepam) is available in scored 1.0 and 2.0 mg tablets in bottles of 100.

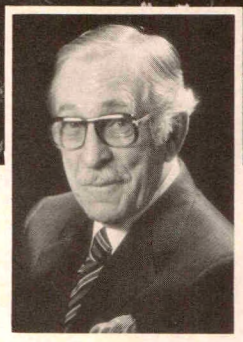
Gillain Manor . . .



A CONCEPT OF RECOVERY OFFERING TOTAL TREATMENT FOR THOSE SUFFERING FROM OR AFFECTED BY ALCOHOL DEPENDENCY

Situated on Mount Newton, Vancouver Island, B.C., GILLAIN MANOR officially opened October 3, 1978. Overlooking restful Patricia Bay, Deep Cove, Georgia Strait, and Mount Baker, GILLAIN blends into the natural environment.

GILLAIN offers the precept of care based on total treatment for patient, spouse, family members and others critical to the patient's continuing sobriety. It is a concept upon which personalities and strengths; physical, emotional, social and spiritual, are reconstructed and relationships between patients and those close to them are effectively rebuilt.

Emphasizing a dignified and honorable approach to the needs of each person, GILLAIN provides those services with qualified personnel vital to the whole recovery of patients and those close to them.

Dr. J. George Strachan, F.R.S.A., LL.D.

J. George Strachan, F.R.S.A., LL.D., founder and Executive Director of GILLAIN MANOR LTD., is internationally known and respected for his contributions to the care of the alcoholic. He is the author of Alcoholism: Treatable Illness, and Practical Alcoholism Programming.

DEPRESSION IN CHILDREN AND ADOLESCENTS

An outstanding, long-awaited volume which critically examines the phenomenon of depression in children and adolescents from a wide range of historical, developmental and clinical perspectives. Recognized authorities from diverse mental health disciplines present the most current research concerning etiology and treatment of depression and assess the relationship between depression and family dynamics. Richly illustrated with case materials, this work offers valuable insight into the treatment of physically handicapped, abused and self-destructive children whose problems often result in profound depression. Also provided is an extensive annotated bibliography containing the most significant clinical and theoretical literature in this recently acknowledged area of child psychiatry.

THE ALCOHOLISMS

Detection, Diagnosis, and Assessment
Afterword by Frank A. Seixas, M.D.

The first book of its kind to focus solely on specialized techniques and materials developed for screening, measuring, and classifying the various forms of alcoholisms, and alcohol-related problems. Based on the author's research and clinical observations in the field, this book suggests that there may be no single, unitary, clinical entity called "alcoholism," but rather a number of varying alcoholisms which differ in their intensity, duration, development, and expression. The author provides information which could have a significant impact on current methods of detecting, diagnosing, and assessing these various alcoholisms.

". . . the only single source to which one can go for an overview of a number of instruments designed to detect, diagnose and assess alcoholism."

—Journal of Individual Psychology

CHARLES C THOMAS · PUBLISHER

WOMEN WHO DRINK: Alcoholic Experience and Psychotherapy *edited by* **Vasanti Burtle,** *Los Angeles, California. Forewords by* **Phyllis K. Snyder, Jan DuPlain** *and* **George Staub.** *(14 Contributors)* This overview of the causes and treatment of alcoholism among women employs a multidisciplinary approach to the problem. The contributors present a variety of provocative ideas and experiences as they discuss gender-specific factors in alcoholism. Special therapeutic applications are given close scrutiny, including a cognitive/behavioral approach, comprehensive psychoanalytic therapy, gestalt therapy, Jungian treatment, and Alcoholics Anonymous. *'79, 370 pp., 3 il., 9 tables, $21.00*

THE DIAGNOSIS AND TREATMENT OF ALCOHOLISM (2nd Ed.) *by* **Gary G. Forrest,** *Psychotherapy Associates, Colorado Springs, Colorado.* The Second Edition of this respected book updates and expands upon the material that made the first edition so valuable. The initial portion of the text discusses individual and social problems associated with alcoholism. Current treatment strategies are then presented: psychotherapy, behavior therapy, Alcoholics Anonymous, residential treatment, marital and family therapy, and disulfiram maintenance. Clinical and research data on such topics as self-disclosure, hidden alcoholics, the alcoholic power fantasy, and the effects of group psychotherapy are presented in the final segment. *'78, 364 pp., 7 tables, cloth-$17.50, paper-$12.95*

THE AMERICAN ALCOHOLIC: The Nature-Nurture Controversy in Alcoholic Research and Therapy (2nd Ptg.) *by* **William Madsen,** *Univ. of California, Santa Barbara.* This forthright text calls into question many of the accepted ideas about alcoholism. It will provide challenging reading for anyone involved in the field. *The Journal of Alcoholism* gave this book a most enthusiastic review: "It was a pleasure to read this thoughtful and scholarly exposition, with its well marshalled facts, and considered opinions, which provide much food for thought and issue many challenges." *'77, 272 pp., 4 il., $13.25*

THE COUNSELOR AND SUICIDAL CRISIS: Diagnosis and Intervention *by* **John L. Hipple** and **Peter Cimbolic.** Detailed information on a variety of related topics will help professionals provide quality treatment for actively suicidal clients. *'79, $9.75*

THE CARE AND MANAGEMENT OF THE SICK AND INCOMPETENT PHYSICIAN *by* **Robert C. Green, Jr., George J. Carroll** *and* **William D. Buxton.** Alcoholism, drug addiction, and psychiatric illness among physicians are among the problems presented. Professional management is outlined. *'78, $10.00*

THE DRINKING DRIVER *by* **Barent F. Landstreet.** Various educational and rehabilitation programs for changing attitudes and behavior in relation to drinking and driving are described. *'77, $12.50*

OCCUPATIONAL ALCOHOLISM PROGRAMS *edited by* **Richard L. Williams** *and* **Gene H. Moffat.** Selected programs representing industrial, utility and municipality settings are presented in detail. *'75, $21.50*

LIFE STRESS AND ILLNESS *edited by* **E. K. Eric Gunderson** *and* **Richard H. Rahe.** Internationally known contributors critically examine relationships between stressful life events and various types of illness. *'74, $22.50*

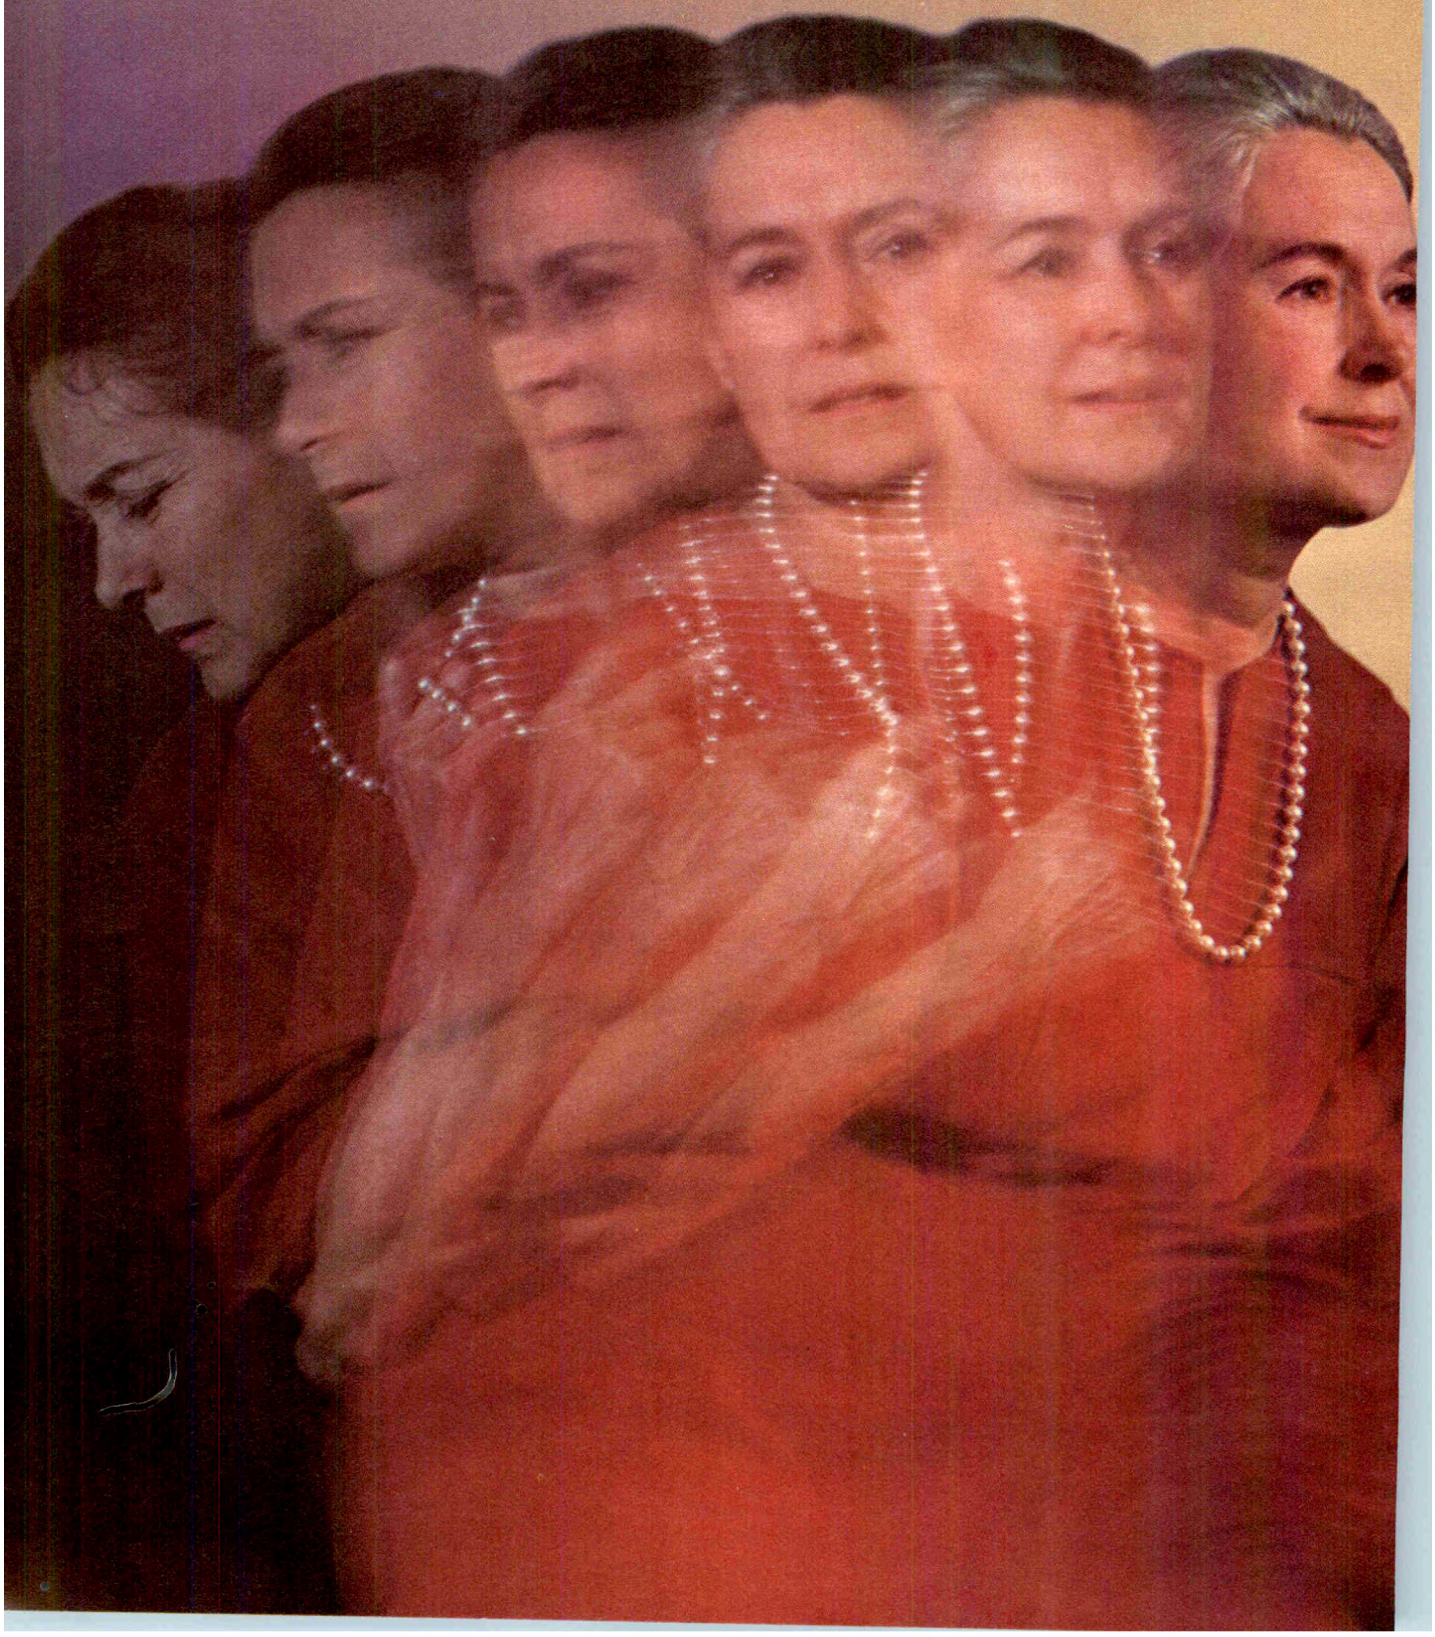
ALCOHOLISM COUNSELING: Issues for an Emerging Profession *by* **Stephen K. Valle,** *Mount Pleasant Hospital, Lynn, Massachusetts. Foreword by* **Harold Hughes.** Significant issues in the emerging profession of alcoholism counseling are reviewed. The author discusses credentialing, professional requirements, a helping model for counselors, ethics and values in counseling, supervision, confrontation, counseling the reluctant and resistant client, and termination in counseling. *'79, 152 pp., 3 il., $13.75*

MANAGEMENT AND ADMINISTRATION OF DRUG AND ALCOHOL PROGRAMS *by* **Marvin D. Feit,** *Univ. of Tennessee, Memphis. Foreword by* **David H. Knott.** This thorough text will help managerial personnel in drug and alcohol rehabilitation programs to fully develop their professional skills. Current concepts, practices and requirements are detailed. The text provides data on the legal, social policy, planning, financial, research, and evaluation aspects of administrative decision making. The self-assessment matrix that forms the core of the text will permit readers to regularly evaluate and improve their knowledge and performance. *'79, 160 pp., 8 il., $13.75*

ALCOHOLISM: The Total Treatment Approach (4th Ptg.) *edited by* **Ronald J. Catanzaro,** *North American Assn. of Alcoholism Programs. Foreword by* **Henry W. Brosin.** *(45 Contributors)* For everyone involved in the treatment of alcoholics, this volume gives a concise but comprehensive presentation of this complex disease and of the great variety of useful treatment methods and settings available. Authorities in the field discuss the total treatment of alcoholism in its three levels of involvement — multidisciplinary, multitherapeutic and multilocational. *'77, 528 pp. (6 3/4 x 9 3/4), 4 il., 23 tables, $26.00*

DRUGS AND THE ELDERLY: Social and Pharmacological Issues *edited by* **David M. Petersen, Frank J. Whittington** *and* **Barbara P. Payne.** Eighteen prominent professionals provide a comprehensive overview of the subject as well as a thorough review of the available literature. *'79, $23.75*

PEOPLE IN PAIN: A Guide to Pastoral Care *by* **James A. Vanderpool.** General counseling considerations are followed by case studies illustrating counseling for atypical feelings and emotional behavior, depression, alcoholism, drug addiction and human sexuality problems. *'79, $12.75*



ACUTE GRIEF AND THE FUNERAL *edited by* **Vanderlyn R. Pine, Austin H. Kutscher, David Peretz, Robert C. Slater, Robert DeBellis, Robert J. Volk,** *and* **Daniel J. Cherico.** This comprehensive text describes the psychological and social impact of bereavement during the period of acute grief. *'76, $19.00*

HUMAN BEHAVIOR AND BRAIN FUNCTION *edited by* **Harvey J. Widroe.** Psychophysiological research is presented as it relates to manic depressive psychosis, alcohol addiction, schizophrenia, and other disorders. *'75, $8.50*

CHILDREN'S EXPERIENCE WITH DEATH *by* **Rose Zeligs.** This lucid text explores the child's developmental concepts of death, the part suicide plays in his or her life, responses to the loss of a parent, and related topics. *'74, $12.50*

PERTOFRANE
(desipramine HCl)

he antidepressant o turn to...

when the first tricyclic fails

"As amitriptyline and desipramine represent the extremes of the differences among the tricyclics, many clinicians start treatment with one or the other and then follow with the alternative drug if response to the first was unsatisfactory."[1]

when side effects are a problem

"Desipramine might be more appropriate for patients who are sensitive to anticholinergic effects or in whom sedative action is not desirable."[2]

when activity is important

"Desipramine seems ideally suited to use in an active ambulatory patient population..."[3]

Psychiatry 135:722, 1978. 3. Barnes, R. J.: Clinical depression: Double-blind study of desipramine and amitriptyline in depressive neurosis, Scientific Exhibit, Southern Medical Convention, Miami, Fla., Nov. 16-19, 1975.

PERTOFRANE® *(desipramine HCl)*

hen the first tricyclic fails

Indication: For relief of mental depression. **Contraindications:** Do not use MAO inhibitors concomitantly or within 2 weeks of the use of this drug. Hyperpyretic crises or severe convulsive seizures may occur with such combinations; potentiation of adverse reactions can be serious or even fatal. When substituting Pertofrane (desipramine HCl) in patients receiving an MAO inhibitor, allow an interval of at least 14 days. Initial dosage in such patients should be low and increases should be gradual and cautiously prescribed. The drug is contraindicated following recent myocardial infarction and in patients with a known hypersensitivity to tricyclic antidepressants. **Warnings:** Activation of psychosis may occasionally be observed in schizophrenic patients. Due to atropine-like effects and sympathomimetic potentiation, use only with the greatest care in patients with narrow-angle glaucoma or urethral or ureteral spasm. Do not use in patients with the following conditions unless the need outweighs the risk: severe coronary heart disease with EKG abnormalities, progressive heart failure, angina pectoris, paroxysmal tachycardia and active seizure disorder (may lower seizure threshold). This drug may block the action of the antihypertensive, guanethidine, and related adrenergic neuron-blocking agents. Hypertensive episodes have been observed during surgery. The concurrent use of other central nervous system drugs or alcohol may potentiate adverse effects. Since many such drugs may be used during surgery, desipramine should be discontinued prior to elective procedures. The potentiation resulting from excessive use of alcohol may increase the danger inherent in a suicide attempt or overdosage. Caution patients on the possibility of impaired ability to operate a motor vehicle or dangerous machinery. Do not use in women who are or may become pregnant, or in children under 12 years of age, unless the clinical situation warrants the potential risk. Because of increased sensitivity to the drug, use lower than normal dosage in adolescent and geriatric patients. **Precautions:** Potentially suicidal patients require careful supervision and protective measures during therapy. Prescriptions should be limited to small quantities. Discontinuation of the drug may be necessary in the presence of increased agitation and anxiety shifting to hypomanic or manic excitement. Atropine-like effects may be more pronounced (e.g. paralytic ileus) in susceptible patients and in those receiving anticholinergic drugs (including antiparkinsonism agents). Prescribe cautiously in hyperthyroid patients and in those receiving thyroid medications; transient cardiac arrhythmias have occurred in rare instances. Periodic blood and liver studies should supplement careful clinical observations in all patients undergoing extended courses of therapy. **Adverse Reactions:** The following have been reported: *Nervous System:* dizziness, drowsiness, insomnia, headache, disturbed visual accommodation, tremor, unsteadiness, tinnitus, paresthesias, changes in EEG patterns, epileptiform seizures, mild extrapyramidal activity, falling and neuromuscular incoordination. A confusional state (with such symptoms as hallucinations and disorientation), particularly in older patients and at higher dosage, may require discontinuation of the drug. *Gastrointestinal Tract:* anorexia, dryness of the mouth, nausea, epigastric distress, constipation and diarrhea. *Skin:* skin rashes (including photosensitization), perspiration and flushing sensations. *Liver:* rare cases of transient jaundice (apparently of an obstructive nature) and liver damage. If jaundice or abnormalities in liver function tests occur, discontinue the drug and investigate. *Blood Elements:* bone-marrow depression, agranulocytosis, thrombocytopenia and purpura. If these occur, discontinue the drug. Transient eosinophilia has been observed. *Cardiovascular System:* orthostatic hypotension and tachycardia. Carefully supervise patients requiring concomitant vasodilating therapy, particularly during initial phases. *Genitourinary System:* urinary frequency or retention and impotence. *Endocrine System:* occasional hormonal effects, including gynecomastia, galactorrhea and breast enlargement, and decreased libido and estrogenic effect. *Sensitivity:* urticaria and rare instances of drug fever and cross-sensitivity with imipramine. **Dosage:** All patients except geriatric and adolescent: 75 to 150 mg./day in divided doses or as single daily dose. Dosage may be increased up to 200 mg. daily. Geriatric and adolescent patients should usually be started with lower dosage (25 to 50 mg. daily) and may not tolerate higher doses. Dosage may be increased up to 100 mg. daily. Lower maintenance dosages should be continued for at least 2 months after obtaining a satisfactory response. Therapy may be given in divided doses or as a single daily dose. **How Supplied:** 25 mg. capsules (pink), bottles of 100 and 1000. Also, 50 mg. capsules (maroon and pink), bottles of 100 and 1000.

SILVER HILL FOUNDATION

A private non profit psychiatric hospital offering an alcohol rehabilitation program which combines the principals of psychotherapy and the philosophy of Alcoholics Anonymous.

The program includes:
- Individual Therapy
- Group Therapy
- Alcohol Counseling
- Education about chemical dependencies
- Family Therapy
- Vocational Guidance
- Occupational and Recreational Therapy

Admissions 9:00 a.m. - 5:00 p.m.
Monday - Friday

203-966-3561

Valley Road
New Canaan
Conn. 06840

Medical &
Executive Director

THE MENNINGER FOUNDATION

Psychiatric Services Within a Caring Milieu

The Menninger Clinic offers comprehensive psychiatric services for individuals seven years old through adult. Each patient receives individualized treatment in a milieu setting via a multidisciplinary treatment team.

Services include:
- Alcoholism Recovery Program.
- Short and long-term residential treatment.
- Diagnostic Services.
- Family, Individual and Group Therapies.
- Emergency Admissions.
- Partial Hospitalization.

a consideration beyond efficacy alone...

Infrequent akathisia and other disabling extrapyramidal effects...

The rapidly rising readmission rate among discharged psychotic patients is mainly due to noncompliance with antipsychotic drug therapy. And this, in turn, may be largely attributed to disabling extrapyramidal side effects, notably akathisia.[1]

Although extrapyramidal effects are characteristic of antipsychotic agents in general, with Mellaril (thioridazine) such effects are infrequent. Adding an antiparkinsonian agent—which can cause its own side effects—can usually be avoided. Mellaril (thioridazine) is contraindicated in patients with severe hypotensive or hypertensive heart disease.

Extrapyramidal Effects of Selected Antipsychotic Agents*[2]

DRUG	EXTRAPYRAMIDAL EFFECTS
Chlorpromazine	Moderate
Perphenazine	High
Prochlorperazine	High
Fluphenazine	High
Acetophenazine	Moderate
Trifluoperazine	High
Chlorprothixene	Moderate
Thiothixene	Moderate
Haloperidol	High
MELLARIL® (thioridazine)	Low

*Based on antipsychotic dosage ranges

Mellaril® [thioridazine]

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

MELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml: thioridazine base equivalent to 100 mg thioridazine HCl, USP

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

THE AMERICAN JOURNAL OF PSYCHIATRY

Editorial: Diverse Research Strategies for Depression and Alcoholism

MOST OF US vaguely recall the poem derived from a Hindu fable that begins, "It was six men from Indostan, to learning much inclined who went to see the elephant (though all of them were blind), that each by observation might satisfy his mind." Each man encountered a single part of the elephant and each described the elephant totally in terms of what he "saw." Hence they "disputed loud and long, each in his opinion exceeding stiff and strong, though each was partly in the right and all of them were wrong."

Recently, when rereading the poem I learned that it was written by John Saxbe, an American poet in the mid 19th century. It was not a child's poem but rather a satire upon parochial religiosity, for it ends with a moral: "So, oft in theologic wars the disputants, I ween, rail on in utter ignorance of what each other mean, and prate about an elephant not one of them has seen."

The moral remains pertinent to our times and to our profession. The elephant we encounter is man with all of his genetic and cultural heterogeneity, and we face the task of understanding his functioning or malfunctioning as an individual and as a member of a family and of a large number of overlapping and sometimes conflicting social groups. It is not likely that any of us can yet fully visualize the elephant, much less understand him completely.

We have advanced considerably beyond the blind men from Indostan insofar as we have new technologies that amplify our senses and scientific methodology with which we can test and replicate our findings. Our actual progress will depend on the degree to which we listen to each other's findings, respect them, and try to integrate them into a comprehensible whole.

Probably no mental illnesses have been studied more thoroughly, with more diverse methods, and with greater profit to our patients than the affective disorders. Yet problems remain and many of these are addressed in the 20 papers on depression presented in this issue. Six employ epidemiological methods, 2 deal with the problems of diagnosis in the very young and the aged, 4 with treatment, 4 with the use of lithium, and 4 with aspects of the biology of depression. There are also 10 papers on alcoholism: 3 deal with the relationship of alcoholism to depression, 1 with the nongenetic familial transmission of alcoholism, 2 with neurophysiological deficits, 2 with issues related to treatment, and 2 with special problems of alcoholic women. Most of the papers are multiauthored and many are the product of interdisciplinary team efforts.

An epidemiological study of depression by Warheit obtained interview data on mental and physical well-being, family and social resources, health and human services utilization, and related social and demographic variables from a large adult population. Three years later he determined through reinterviews the degree to which depressive symptomatology appeared. He found that the best predictor of ensuing depression was the degree to which it existed initially. This suggests that depressive symptomatology may be a trait; whether this is biological, characterological, or both is not known but it seems to predispose such individuals to life events that may exacerbate their depression. Not so surprisingly, persons in low socioeconomic groups are most vulnerable; they have fewer resources to begin with and experience more losses. The study documents the degree to which per-

0002-953X/79/05/0497/05/$00.50 © 1979 American Psychiatric Association

sonal, familial, and interpersonal resources can mitigate some of the adverse effects of losses. Motto's epidemiological research generates two models of people at especially high risk for suicidal behavior. He interviewed 3,000 patients admitted to a psychiatric inpatient unit because of a depressive or suicidal state. This population has an expected suicide rate of 1%–2% a year. Two groups were found that committed suicide at a rate above 4% during the follow-up period. One of these was males under 40, the other consisted of individuals who were stable in their health, work, and marriage but who had imposed on them a significant loss or threat of loss. These two models fall far short of the number required to include the bulk of the very high-risk suicidal persons, but it is an encouraging beginning and demonstrates a research method that may be continually useful in generating still other models. Dunner and coworkers examined the question of the degree to which life events can precipitate episodes of illness in patients with bipolar disease. Fifty percent of such patients report significant life events within three months of their first episode of illness. Once the pattern of the illness was established it seemed to achieve its own autonomy, and life events were not significantly related to subsequent episodes. It might be expected that the 50% who failed to report external precipitants might be more heavily genetically loaded, but Dunner's study of the relatives of these patients showed this not to be the case.

Goldberg and coworkers addressed the question of whether depressed mood is a precursor of serious illness. Over a two-year period a large number of subjects from two areas of the country were sampled to assess their physical health and degree of depression. A year later the subjects were reinterviewed. Persons who died or developed serious physical illness requiring hospitalization had no more depressive symptoms before becoming ill than the controls who remained well.

The two remaining epidemiological papers deal with more specialized populations. Helzer and coworkers conducted a followup study of Viet Nam combat veterans who had been depressed a year after their return and found the depression to be short-lived. Preservice experience apparently plays a stronger role in long-term psychological adjustment. Beckman and coworkers found that depression occurs in the wives of nuclear submarine personnel whose husbands are essentially incommunicado while at sea for three-month intervals twice yearly. The problem is important not only to the Navy but is of considerable theoretic interest because the phases of maladaptation that lead to depression among these women are described.

Depressive symptomatology may differ from the usual in both the elderly and the very young. Cavenar and coworkers offer brief case histories of four patients with depression mimicking organic brain syndrome that responded dramatically to pharmacotherapy. Philips describes the symptoms of depression in infancy, preschool years, and the early school years. Acknowledging the diversity of etiological factors that may contribute to childhood depression, he highlights the interpersonal ones. Depressed parents are unable to meet the needs of the child and this may result in depression in the child.

In the four papers dealing with therapy, Rivinus and Harmatz report on manic-depressive illness in the institutionally retarded. The age of occurrence, the frequency in their families, and their response to lithium is similar to that of patients with normal intelligence. Nelson and coworkers report that tricyclics may exaggerate the existing delusions of unipolar delusional depressed patients. They respond well to the addition of phenothiazines or to ECT. Avery and Lubrano reconsider data from a large Italian study that compares ECT with imipramine in high doses. These data show that ECT is superior for delusional depressions and for the most severe clinical depressions; it is inferior for neurotic and reactive depressions. The paper brings to mind the thought that the usual indications for ECT are patients who have had drug failures, those whose occupations or professions do not permit prolonged hospitalization, the severely depressed and suicidal, the aged, and those who are too medically ill to withstand the adverse medical effects of drugs. We tend to avoid ECT because we assume that the risks outweigh the benefits, but if this really is the case, why do we use it on the old and frail? The risk benefit ratio for modern ECT compared with drugs requires reevaluation.

The article by Weissman and coworkers on the efficacy of combined pharmacotherapy and psychotherapy in the treatment of acute depressive disorders is most stimulating. Common sense suggests that combined treatment should be more effective than either component alone because a biological diathesis for depression is well established, antecedent psychosocial stresses are frequently found, and coexisting problems in interpersonal relationships are the rule in depressed patients. The efficacy of drug treatment has been well established in a large number of controlled clinical trials. The efficacy of insight-oriented psychotherapy has not been as rigorously documented. Recently there have been claims that cognitive therapy is more effective than imipramine in depressed outpatients, but it is not yet clear whether this would be true for patients whose illness is of the type or severity to require hospitalization. While combined therapy is commonly used, pharmacotherapy and psychotherapy remain competitive ideologically. Moreover, there is surprisingly little empirical evidence that the effects are additive or synergistic.

In this 16-week study by Weissman, amitriptyline, weekly interpersonal psychotherapy that focused on the social context of the depression, and their combination was compared with psychotherapy, which was not scheduled but was made available if the patient called. All of the active treatments were better than the nonscheduled treatment. By all criteria the combined treatment group did better than either treatment alone. We can hope that there will be more well-designed research with other populations, other illnesses, other drugs, and other forms of psychological treatment alone and in combination. Research on the combination of cognitive therapy and pharmacotherapy for depression is certainly in order.

Among the 4 papers dealing with biology, that by Oliveau and Willmuth finds that noninvasive electromyography of the facial muscles is a sensitive indicator of affect-laden memories and images. It is, however, unable to detect differences between depressed and nondepressed subjects. Lykouras and coworkers find a correlation between plasma levels of cyclic adenosine monophosphate and mood in manic-depressive patients but note that since other factors such as anxiety may also influence these levels the exact association warrants more detailed exploration. Garfinkel and coworkers employed a peripheral decarboxylase inhibitor (carbidopa) to separate central nervous system metabolites of the biogenic amines from peripheral metabolites. In a carefully controlled metabolic study they obtained data that suggest a distinct profile of indolamine and catecholamine metabolism in unipolar depressed subjects but not in bipolar patients. They submit the hypothesis that the fundamental defect in these patients may lie in the reduced capacity of their brains to take up tryptophan, the amino acid precursor of serotonin. They suggest that lithium, which increases brain tryptophan uptake, might be combined with tryptophan in clinical trials of the antidepressant effectiveness of amino acid. A neuroendocrinological study by Brown and coworkers confirms previous findings that depressed patients show resistance to the suppression of cortisol secretion following dexamethasone. Their data show a general trend for an association between a good response to tricyclic treatment and the capacity to escape dexamethasone suppression.

Among the four papers dealing with the use of lithium, that of Steinberg suggests, on the basis of retrospective studies of lithium responders, that there is an MMPI profile that may help to prospectively predict them. The article by Belmaker and coworkers demonstrates that lithium diminishes the accelerated heart rate which usually accompanies mental arithmetic tasks without affecting the resting heart rate. They hypothesize that this correlates with the finding that lithium does not inhibit basal adenylcyclase activity but does inhibit noradrenaline-induced rises. They suggest that lithium may be useful in case of paroxysmal atrial tachycardia in patients with healthy hearts. The paper by Kocsis and Stokes retrospectively examines the quality of the outcome in a large number of patients maintained on lithium for a mean of somewhat more than four years. Among other things they find that there are lower plasma lithium levels in patients who experience both depressive and manic episodes. They suggest that this may reflect the practice of some patients to decrease lithium when depression occurs, thus creating a vicious cycle with rebound mania. A longitudinal case report by Ereshefsky

and coworkers suggests that red blood cell lithium concentrations correlate better with suppression of tardive dyskinesia, neurotoxicity, and changes in manic symptomatology than does plasma lithium. Further study of the utility of lithium for the distressing problem of tardive dyskinesia based on erythrocyte levels seems warranted.

There are many reasons for suspecting a relationship between alcoholism and depression. Keeler and coworkers studied the prevalence of depression after alcohol withdrawal in a population of 35 male alcoholics about a week after admission to a VA alcoholism treatment service. They found that the prevalence depended on the method used for diagnosis. On clinical grounds 8.6% were considered depressed, with the Hamilton Rating Scale it was 28%, the MMPI depression scale 43%, and the Zung Self-Rating Scale 66%. These authors emphasize that the diagnosis should be made solely on clinical grounds and that rating scales can be used to measure change once the diagnosis has been made. This is important because if depression is overdiagnosed in alcoholics, tricyclic antidepressants and lithium can be overused for treatment and prophylaxis. The study of Hamm and coworkers deals with military personnel referred solely because of excessive drinking. They employed a Hamilton Rating Scale and a self-rating depression scale and found the level of depression to be much lower than that reported by others for alcoholics. They emphasize that their patients were all on active duty and were not referred because of psychiatric problems. They suggest that the low incidence of depression in their alcoholics may more closely resemble that of alcoholics in the population at large because the majority of such patients do not seek treatment. Dunner and coworkers studied alcoholism in a large population of well-defined manic-depressives. About 20% of the men had alcohol-related problems but none of the women did. The relatives of manic-depressive patients were more prone to alcoholism than are those of the control group. Although genetic data for transmission of alcoholism are sound, it is quite clear that genetics alone cannot account for the transmission. Roland and coworkers found that families which maintained their patterns and rituals even in the face of a serious parental alcoholic problem are less likely to transmit alcoholism into the children's generations than those whose patterns are disrupted.

Hill and coworkers used a CT scanner and the Halstead-Reitan Neuropsychological Battery and found surprisingly little evidence of ventricular enlargement and cerebral atrophy but, nonetheless, evidence of neuropsychological damage. Fine and Steer examined 100 men arrested for drunken driving several days after they had stopped drinking and found evidence of short-term spatial memory deficits that might influence their capacity to remember road signs, traffic alerts, or emergency signals. Thirty percent had previously been arrested for drunken driving, but only 10% had been treated for alcoholism.

Two papers by Schuckit and Morrissey address some problems of alcoholic women. Fourteen percent have primary affective disease and many abuse other drugs. Two-thirds of these women had received prescriptions of hynoptic and antianxiety drugs while actually abusing the drugs. They urge that hypnotics, stimulants, and antianxiety drugs should almost never be prescribed to outpatient alcoholics.

Two papers deal with treatment: Mathew and coworkers suggest that the craving of sober alcoholics for liquor is largely a conditioned response to environmental stress, that it diminishes with continued abstinence, and that it can be relieved by psychological methods. The article by O'Leary and coworkers emphasizes that the degree to which the staff rates patients as high on interpersonal attractiveness is the major determinant in their acceptance or rejection for continued treatment.

This brief summary and comments hardly do justice to the quality and diversity of the 30 papers. I hope it transmits the sense of vigor with which research is being conducted. Psychiatry, so long dominated by lofty and competing theoretical structures, requires honest brick-laying to create the complex home in which we can comfortably work, live, and evolve.

I conducted an informal and nonscientific survey of my colleagues and was unable to find any who had ever read every article in a journal issue. Nor had I, until confronted with the task of writing this editorial. I not only profited from

learning about work in areas that I have tended to ignore but even enjoyed it. I suggest that the readers of the journal do the same for at least one issue. It might get to be a profitable habit. There is much to be learned by listening to each other.

Life Events, Coping, Stress, and Depressive Symptomatology

BY GEORGE J. WARHEIT, PH.D.

The author presents data on the relationships between life events, coping resources, and depressive symptomatology. A probability sample (N=517) was interviewed three years apart. Respondents with high life-event scores had significantly more depressive symptomatology than those with low scores. Those with personal, familial, and interpersonal resources had significantly less depressive symptomatology than those without such resources in both the low- and high-life-event groups. The best predictor of Time 2 depressive symptom scores was Time 1 symptom scores; losses and resources were also statistically significant factors. These findings demonstrate the complex interrelatedness of life events, coping resources, and depressive symptomatology.

THE RELATIONSHIPS between social, psychological, and other environmental factors and illness have been of research interest to medical and social scientists for a long time. This interest has accelerated in recent decades as investigators from a wide range of disciplines have attempted to identify the processes by which stressors act as precursors to physical and/or mental disorders. Although there have been almost as many definitions of stress as there have been researchers, there is a common theme in them. Stress is generally conceptualized as the altered state of an organism produced by agents in the psychological, social, cultural, and/or physical environments. It is assumed that this altered state, when unmitigated, produces deleterious effects on the physical and/or mental well-being of affected individuals.

Among medical scientists, the early work of Cannon (1) was very influential. His pioneering efforts to detail the relationships between emotional states such as fear, anger, pain, and anxiety and changes in body function provided a model for early scientific inquiry. In psychiatry, Adolf Meyer (2) emphasized the role of life events in the development of physical and mental disorders, and Selye's work (3, 4) has made very important theoretical contributions to our understanding of the physiological adaptations to stress. Hinkle (5, 6), Wolff (7), and their colleagues working in the area of psychosomatic medicine also made early contributions as they investigated the links between stressors and illness. Recently, many researchers have attempted to establish the qualitative and quantitative relationships between particular classes of life events and illness behavior. The efforts of Rahe and Holmes (8, 9), Paykel and associates (10, 11), Dohrenwend and Dohrenwend (12, 13), Myers and associates (14), and Brown and associates (15) are particularly well known.

The research findings dealing with stress and illness are voluminous, comprehensive, and broadly published. The number of empirical investigations reporting on coping behaviors as they relate to stress and illness are quite limited, although an increasing number of publications reflect a growing interest in the issue (16–21).

The first purpose of this paper is to report empirical data on life events, coping resources, stress, and depressive symptomatology. The second objective is to analyze these same variables within the context of longitudinal data that permit comparisons of depressive symptomatology before and after the occurrence of 23 loss-related life events.

THEORETICAL MODELS

Early research relating life events to psychosocial stress and illness tended to regard the relationships in a simple stimulus-response, unicausal manner. This oversimplified model has more recently been refined to include coping and adaptation variables that are seen as intervening processes, buffering the individual from the damaging effects of stress-producing life events.

Although stress-illness models have become more sophisticated in the past decade, many of them still have serious theoretical deficiencies, e.g., stressful events, coping, and illness continue to be conceptualized as static and occurring within a closed system. As such, these models do not provide a theoretical understanding of the dynamic interactions of an organism as it influences and is influenced by its environments. The scientific problems posed by closed models are not

Revised version of a paper presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received May 22, 1978; revised Oct. 10, 1978; accepted Nov. 14, 1978.

confined to their theoretical inadequacies; they have inherent analytic weaknesses as well. Statistical models that assume unidirectional causality, e.g., path analysis, are basically inadequate since they do not provide for the testing of reciprocal interactions between the variables being analyzed. As a consequence, they do not take into account the systemic relationships inherent in the real world as organisms affect and are affected by their psychological, social, ecological, and cultural milieus.

The limitations of these early models led to the formulation shown in figure 1. This model constituted the theoretical framework that guided our efforts to test the relationships between life events, coping resources, stress, and depressive symptomatology. Events are seen as arising from the following three sources: the individual's psychological and biological constitution, the culture, and the social environment. The events section of the model includes the specific events commonly associated with the literature on stress and crisis events.

The adaptive-nonadaptive screens represent the coping resources available to individuals as they attempt to meet the demands placed on them by life events. These screens include the individual's personality, biological constitution, and genetic predispositions. They also include coping screens provided by the culture. Parsons (22) described some of these as supra-empirical referents and suggested that their function was to afford culturally defined and transmitted systems of belief that give persons sources of *explanation* for events that cannot be accounted for by a society's logic or science. The culture also provides symbolic definitions that attach *meaning* to events. The personal resources available to individuals confronted by life events are seen as their socioeconomic statuses, families (both nuclear and extended), interpersonal networks, and the secondary organizations provided by the broader social environment.

Life events, stress, coping behaviors, and illness are most usefully studied as a process. Characteristically, when a crisis event occurs, we hypothesize that the individual's first line of defense is his or her psychological, physical, and genetic makeup. If the individual is unable to deal with the demands occasioned by the event, he or she then customarily seeks to extend his or her sources of support, most commonly calling for assistance from spouse, children, parents, or other family members. If these resources are unavailable or inadequate, the individual often turns to interpersonal networks, that is, to friends in whom he or she can confide and go to for help. The theory suggests, further, that when the person's individual and personal resources are insufficient to meet life-event demands, the next step involves seeking assistance from professional persons or agencies. If these prove to be inadequate, the individual may then turn to his or her culturally provided beliefs, values, and symbols. In practice, of course, when confronted with crisis-related demands, individuals normally seek to maximize all available resources simultaneously and in a complementary manner.

FIGURE 1
Life Events: Sources, Adaptations, and Outcomes

In the model, stress is conceived as an altered state of an organism and occurs when the demands on an individual exceed his or her capabilities to respond. The degree of stress experienced is a function of the number, frequency, intensity, duration, and priority of the demands viewed in apposition to coping resources. The demand-capability ratio is seen as dynamic (and, as such, fluctuating), multisystemic, and temporal. As shown in figure 1, psychosocial stress is conceptualized as being different from the events that may precipitate it. Events are seen as agents, and stress is viewed as an altered state of the organism. Stress is different from its outcomes, which are viewed as being symptoms, syndromes, and/or social dysfunction.

The theoretical model presented in figure 1 is designed to reflect the systemic nature of life events, coping mechanisms, stress, and stress outcomes as they occur in a temporal context.

DESIGN OF THE STUDY

The data reported are from a major two-stage epidemiological study of mental health needs and services that is being conducted in the southeastern United States. A statistical probability sample of 1,645 adults was interviewed by means of a 317-question interview schedule. The schedule included an extensive inventory of items, scales, and indexes designed to obtain data on mental and physical well-being, health, the utilization of health and other human service agencies, personal, familial, and social resources, and related social and demographic variables. A 517-person subsample of the original respondents was reinterviewed three years after the initial contact. The two interview schedules were essentially the same; one exception was the inclusion of a slightly modified version of the Paykel life event items in the follow-up instrument (10, 11).

In this research the independent variables were loss events and Time 1 depression scores. The intervening variables were personal coping resources, consisting of spouse, family, friends, socioeconomic status (SES), and professional persons and/or agencies. The dependent variable was Time 2 depression scores.

The depression scores were determined by use of a factor analytic scale conceptualized as containing five dimensions: affective symptoms related to lowered mood; somatic symptoms; altered patterns of psychobiological reactivity such as sleep, appetite, and libido; negative self-evaluation including lowered self-esteem, self-blame, suicidal ideation, and guilt; and an existential dimension typified by pessimism, despair, and a gloomy outlook of the future. Using this conceptualization, an 18-item scale was developed. Cronbach's alpha (as reported in 1951) was computed as a test of reliability; the alpha coefficient was 0.8399, well above the limit accepted for scalability. Since its development the scale has been administered to probability samples of approximately 5,000 adults living in the southeastern United States. Analysis of scores for various social and demographic groups in these samples also suggests high levels of scale reliability (23–25).

Data on coping resources were obtained as part of each survey. Both interviews included a large number of questions related to personal, familial, social, and cultural resources and their use.

The SES scores were calculated following the methodology suggested by the Bureau of the Census and modified by Nam and associates (26). The SES score was the average of ranks of an individual's education, income, and occupation scores. For purposes of this paper the sample scores were arranged in quintiles and were then placed into one of two categories. Those in the lowest three quintiles were put in the low SES group, and those in the top two quintiles in the high group.

Levels of loss were determined by scores on 23 items from the Paykel inventory. Only events occurring between the Time 1 and Time 2 interviews were included. The items selected were all associated with loss, a condition highly related to depressive symptoms and syndromes. The items included events such as the death of a child, spouse, and/or close family members; marital separation; and retirement. The 23 items were weighted using the method provided by Paykel and Uhlenhuth (11). Each respondent was assigned a total loss score on the basis of the number and kinds of losses. The weighted mean of the loss scores for the sample was 28.31. After preliminary analysis the sample was dichotomized into a low/moderate-loss group and a high-loss group; those with scores of 0–32.99 were placed in the former category, and those with scores of 33 or above into the latter group. Approximately one-third of the 517 respondents were in the high-loss group.

The methods of analysis included analysis of variance, t tests, and multiple regression equations.

FINDINGS

Relationship Between Depression Scores, Resources, and Losses

The findings relating depression scale score means, resources, and level of loss as determined by the 23 Paykel life-event items are presented in table 1. In every instance those in the high-loss category, regardless of the presence or absence of personal resources, had significantly higher depression scale scores than those in the low/moderate-loss group. The data also suggest that the presence of resources significantly mitigates the impact of losses associated with life events. All persons in the high-loss category had significantly higher depression scores than those in the low-loss group. Personal resources were shown to significantly lessen the impact of loss except when the resource was close relatives nearby.

The utilization of physical health services as determined by visits to physicians, clinics, and agencies was significantly greater for those in the high-loss group. The one exception was for those utilizing mental health services; score differences between the two groups were not statistically different. However, the numbers are quite small, and this finding requires cautious interpretation.

The presence of resources as determined by SES was significant within and between groups. The highest depression scale scores in the entire sample were found among those in the high-loss group without friends nearby to help and among those in the high-loss, low-SES groups. The data also show that individuals with low SES experienced more life-event losses than those with high SES. Approximately two-thirds (64.7%) of all those with low SES were in the high-loss group; by contrast, only 31.2% of those with high SES were in the high-loss group.

Estimation of Depression Scores from Losses and Resources

When the data were analyzed by means of a regression equation designed to estimate depression scores from losses and resources (including SES), the overall regression was significant at the $p<.001$ level. Low SES, the absence of a spouse, and high loss scores were most significantly correlated with high depression scores. The presence of friends was a significant variable ($p<.01$), as was the utilization of psychiatric services ($p<.01$). The cross-product interaction term formed from loss and SES was also significant ($p<.01$); the other interaction terms were not significant. The overall variance accounted for by the terms in the equation was 27.2%.

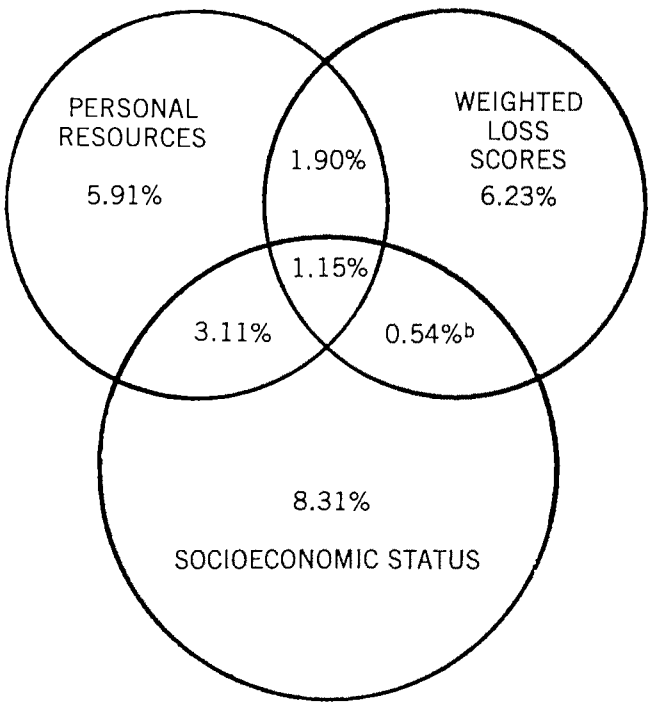

Figure 2 displays findings from a series of regressions that include terms for losses, resources, and SES. It shows that SES accounted for the greatest amount of variance; this variable accounted for 13.11% of the total explained variance. Of this total, 4.80% was shared with other resources and losses. The presence of resources accounted for a total of

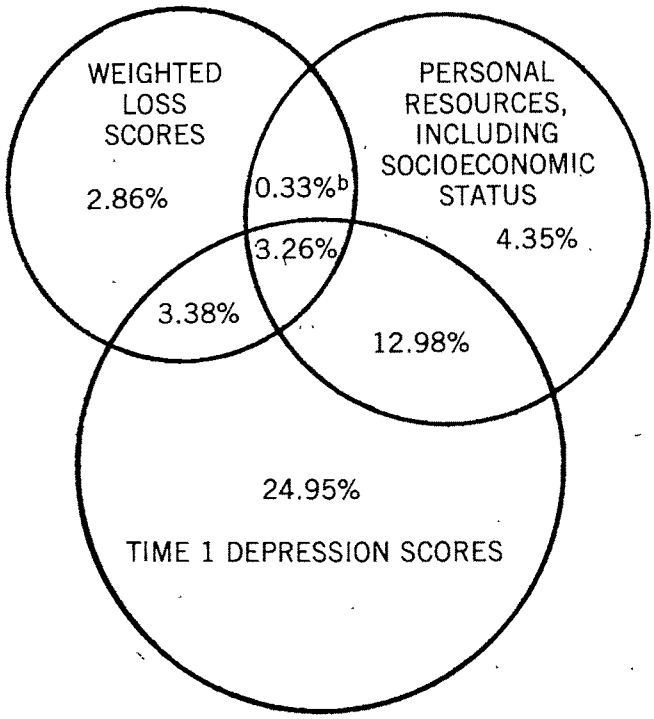
[b]An interaction term for Socioeconomic Status × Loss is included in the model.

12.07% of the variance, with 6.16% of this being shared with losses and SES. The loss scores accounted for 9.82% of the variance, with 3.59% of this total shared with resources and SES. The data in figure 2 indicate that resources were more powerful predictors of depression scores than were the life-event-loss scores.



Relationship Between Time 1 and Time 2 Depression Scores, Losses, and Resources

Since there were depression data on each respondent at two points in time, it was possible by means of regression analysis to examine the relationships between Time 1 and Time 2 depression scores, losses, and resources. The findings indicate that the Time 1 depression scores accounted for about half of the variance associated with Time 2 scores. High-loss scores were statistically significant in the equation ($p<.001$); receiving psychiatric care and SES variables were also significant ($p<.01$), but they accounted for much less of the explained variance. Presence of friends was not significant. The overall equation was significant ($p<.001$). The total variance explained was 52.11%.

As figure 3 illustrates, the Time 1 depression scores accounted for 44.57% of the explained variance, with 16.24% of this being shared with resources (12.98%) and losses (3.38%). Resources, including SES, accounted for 20.92% of the variance, 4.35% of which was unique. Losses contributed 9.83% to the variance explained; 2.86% was a unique contribution.

The findings presented in figure 3 have significant theoretical implications. The data indicate that much

FIGURE 3

[b]An interaction term for Socioeconomic Status × Loss is included in the model.

depressive symptomatology is stable over time and that it is relatively independent of both coping resources and life-event losses. The availability of resources and the occurrence of loss-related life events are not discounted by the findings; they are statistically significant in the equation. However, the amount of unique variance accounted for by each is much smaller than that predicted by the Time 1 depression scores. Finally, the interrelatedness of depression scores, resources, and loss events empirically corroborate the theoretical model that guided the research.

SUMMARY AND CONCLUSIONS

This paper has presented data on life-event losses, coping resources, and depression scores, as well as data on a second issue relating the stability of depressive symptomatology over time to losses and resources. The major findings of the research can be summarized as follows.

1. Persons having high loss scores had higher depression scores than those with low/moderate loss scores.

2. The presence of a spouse was significantly correlated with lower depression scores for both the low/moderate- and high-loss groups. The presence of other relatives nearby was not significant.

3. The availability of friends was significantly correlated with lower depression scores for the high-loss group; no significant differences were found for the low-loss group.

4. Significantly more of the high-loss group were using the services of physicians and clinics than were those with low losses.

5. Those utilizing mental health services in both loss groups had higher depression scores than the nonutilizers.

6. Low socioeconomic status was significantly correlated with higher depression scores in both loss groups. It was also found that 64.8% of those in the low-SES group were in the high-loss group, compared with 31.1% of those in the high-SES group. The data suggest that low SES places persons in double jeopardy; they have fewer resources with which to cope and experience more losses.

7. A series of regression equations showed that losses and the absence of resources were significant variables when used to predict high depression scores.

8. The Time 1 depression scores accounted for more explained variance in Time 2 depression scores than did losses or resources.

9. There was considerable overlapping (interrelatedness) of variance explained by losses, resources, and Time 1 depression scores as predictors of Time 2 depression scores.

The data presented illustrate the complex nature of the interrelationships between life events, coping resources, and depressive symptomatology. The findings suggest that while life-event losses and the absence of personal and social resources are related to high depression scale scores, other factors are statistically (and probably theoretically) more important sources of explanation of depressive symptomatology. For example, the finding that Time 1 depression scores were the best predictor of Time 2 scores suggests that for some persons, at least, depressive symptomatology is a trait condition that may predispose them to life events which in turn exacerbate their preevent levels of psychiatric distress. The data also indicate that life-event losses are mitigated somewhat by the availability of personal, familial, interpersonal, and other resources; this finding has implications for early therapeutic intervention designed to assist those experiencing significant life-event losses.

Finally, the theoretical and analytical model used to guide the research appears to have utility for investigators seeking to understand other dimensions of the phenomenon of life events, coping resources, and illness.

Life Events at the Onset of Bipolar Affective Illness

BY DAVID L. DUNNER, M.D., VIJAYALAKSHMY PATRICK, M.D., AND RONALD R. FIEVE, M.D.

The authors assessed the occurrence of stressful life events before the initial or subsequent episodes of affective illness in a group of 79 bipolar I manic-depressive patients who were attending a lithium clinic. About half of the patients recalled a life event in the 3-month interval before their initial episode; postpartum onset was prominent among these events. Few patients recalled life events for subsequent episodes. Finally, history data did not differentiate patients who recalled life events and those who did not. These data may be useful in assessing environmental antecedents of populations at risk for bipolar illness.

THE ROLE of stressful life events in the etiology of affective episodes has been speculated on and studied by many psychiatrists. Environmental events considered as possible precipitants of affective episodes have included interpersonal relationships (1); bereavement and social factors (2); arguments with spouse, marital separation, starting a new type of work, change in work conditions, and personal illness (3, 4); and problems in job performance and increased work responsibility (5). Some studies have noted that stressful environmental events are noted more frequently before initial affective episode than subsequent episodes (4, 5), and one study reported stressful life events before the initial episodes of two rapid-cycling patients (4). There has been no consistency among these studies regarding the temporal relationship between the life event and the onset of the affective episode. This time interval has ranged up to 3 years (2).

Hudgens and associates (6) found that 10 of 40 affectively ill patients in a controlled study had a precipitating life event within 6 months before the index episode. Similar associations for previous episodes of illness were rare. In addition, they found that the observed rate of life events before an affective attack in these 40 patients was not significantly greater than that in a control group of hospitalized patients. However, they noted more frequent changes of residence and a higher incidence of reported interpersonal discord in the group with affective disorders. These occurred during the year before admission but after the onset of affective symptoms. The authors concluded that when the illness seemed to begin soon after a stressful event, the temporal relationship might be purely random.

We attempted to study the relationship of life events to the onset of illness and to subsequent episodes in bipolar patients. We also analyzed family history data from these patients to ascertain if the subjects who reported life events associated with illness onset showed less familial incidence of affective illness than patients who did not report such events. We were also interested in assessing the frequency of postpartum onset and postinfluenza onset as specific possible precipitants.

METHOD

The sample consisted of 79 patients (41 men and 38 women) from the Lithium Clinic of the New York State Psychiatric Institute. All patients were evaluated by two psychiatrists and met the criteria for primary affective disorder (7). All had been hospitalized at least once for mania and were classified as bipolar I (8). Eleven of these bipolar I patients were "rapid cyclers," i.e., they had four or more affective episodes a year (9). All patients voluntarily consented to participate in this study.

All patients were requested to complete a questionnaire that included a list of life events. This list was prepared by assessing the records of over 200 former clinic patients and determining life stresses that were recorded as being of possible relevance to their affective episodes. Any events that occurred during the 3 months before the initial affective episode were noted as possible precipitating factors. The events included 1) accidents, operations, or physical illness, 2) occupational and financial changes, 3) illness, death, accidents, or separations in the family, 4) interpersonal conflict at home, school, or work, 5) marital changes, 6) pregnancy, postpartum state, or menopause, 7) change of residence or country, and 8) patients' spontaneous assessments of any other impor-

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977; received May 4, 1977; revised Jan. 3, 1978; accepted Feb, 10, 1978.

tant or stressful occurrence preceding their illness. Life events relating to subsequent episodes were also noted. Concurrently, each patient was interviewed by a psychiatrist, and care was taken to exclude events that were reported during the illness and those that had occurred more than 3 months before the episode or onset. The age at onset of illness and the nature of the initial episode were also determined.

Family history data were obtained from clinic records, research records, and through direct interviews of probands' relatives. Most patients had participated in genetic studies that included structured interviews (10) of relatives, performed by individuals who were blind to proband diagnosis. Of 259 first-degree relatives (parents and siblings), 63 had been interviewed. Of the remainder, 49 were deceased. In addition, other relatives (e.g., children and spouses) of many patients had been interviewed and gave information about psychiatric illness in other first-degree relatives of the proband. Assessment of family history was performed independently of and blind to the subject's life event status.

TABLE 1
Demographic Data for Bipolar Patients With and Without Life Events

Group	N	Age		Age at Onset	
		Mean	SD	Mean	SD
Men					
With life event	21	43.5	10.7	29.1	8.8
Without life event	20	51.2	14.9	25.1	13.6
Women					
With life event	20	44.4	15.0	26.1	8.1
Without life event	18	44.9	13.6	24.7	8.5

TABLE 2
Life Events Reported at Onset of Illness by Nature of Onset

Group	Type of Onset	
	Depression	Mania
Men[a]		
Reported life events	5	16
Did not report life events	14	6
Women		
Reported life events	16	4
Did not report life events	9	9

[a]For the distribution for men $\chi^2=7.1$, $p<.01$ (Yates' correction applied).

RESULTS

About half of the patients described life events before the onset of their initial episode. There were no significant differences in the mean age of patients or the mean age at onset of illness for patients who described life events and those who did not (table 1).

Thirty-five of the 79 patients had initial manic episodes, and 44 patients had depressive onsets (see table 2). For patients whose first episode was manic, a greater percentage of men than women reported life events at onset of illness. The reverse was true when the initial episode was depressive. There was a significant difference in type of onset between men who reported life events and those who did not. However, similar results were not shown for women.

The frequency of life events at the onset of illness is presented in table 3. Several patients noted multiple events. Difficulties at work, marital problems, interpersonal conflict, and postpartum events ranked among the most frequently reported. Difficulties at work and interpersonal conflicts were reported more frequently by those who had mania as their first episode. Postpartum state and surgery as preceding life events were reported only by patients with depressive onsets. It is worth noting that 7 patients with manic onsets described increased responsibilities at work before the onset of their manic episode. Influenza as an event preceding the first episode was reported by only 1 patient in our study. Two patients related their first episodes to appendectomy and thyroidectomy.

There were 3 men and 8 women rapid cyclers. None of the men reported life events before their onset of illness, whereas 5 women had a preceding event. In 3 of these 5 patients the onset of illness occurred postpartum. However, a postpartum onset was not significantly more frequent among those who were rapid cyclers than those who were not.

TABLE 3
Frequency of Life Events at Onset of Bipolar Illness

Life Event	Type of Onset		Total
	Mania (N=20)[a]	Depression (N=21)[a]	
Difficulties at work	8	5	13
Marital problems	4	5	9
Interpersonal conflicts	8	3	11
Postpartum	0	8	8
Pregnancy	2	0	2
Illness in family	2	0	2
Accident	1	1	2
Operation	0	2	2
Influenza	1	0	1

[a]Some subjects reported more than one life event.

Subsequent Episodes

Twelve patients reported life events that occurred before subsequent affective episodes; seven of them had not reported events at the onset of illness. Two of these patients reported marital problems. Difficulties at work, interpersonal conflicts, postpartum episodes, illness in the family, and flu were reported by one patient each.

Family History Studies

Family history data were available for 68 patients. Family histories were recorded as positive for affective disorder if a parent or sibling 1) had been hospitalized or treated for mania or depression or 2) had depressive symptoms and had not been treated but met criteria for cyclothymic personality or depressive

personality (11). Of patients who reported life events at onset of illness, 72.7% had a positive family history for affective disorder compared with 68.7% of patients who did not report onset events. This difference was not statistically significant. Morbidity risks for bipolar and unipolar illness among these first-degree relatives were calculated and found to be similar for patients with life events at onset of illness and those without. Even when illness in relatives was considered present only if treatment had been received, the morbid risks in relatives for bipolar I, bipolar II, and unipolar illness were similar for the two groups.

DISCUSSION

The population we selected for this report has rather strictly defined bipolar manic-depressive illness and has been extensively studied from many points of view. Contrasts between bipolar I patients and other affectively ill patients on diverse measures such as symptomatology, clinical course, pharmacologic response, and biochemical characteristics have been reported (11, 12). Of interest is the high familial loading of affective illness, particularly bipolar illness, among relatives of bipolar I probands. The increased risk for affective illness in relatives has supported the notion of a genetic component in the etiology of bipolar I illness (13).

Thus in view of this presumably large genetic component in the etiology of bipolar I illness, our finding that about half of these patients had a life event at the onset of their illness which could be related to etiology suggests several possibilities. There may be a genetic-environmental interaction in the onset of symptomatology of bipolar illness, or the life events might be randomly related to onset or symptomatic of the illness. Some stresses, such as increased interpersonal conflict, could represent symptoms of illness (a view taken by Hudgens and associates [6]). Other stresses, such as influenza and surgery, occurred so infrequently that their relationship to the onset of bipolar illness was probably one of chance. However, childbirth is a specific event that can be accurately dated in relation to onset of affective symptoms. Our data confirm a study by Baker and associates (12) relating childbirth as an important factor in the onset of bipolar depression among women. It seems to be more difficult to demonstrate events of similar importance in men that relate to onset of illness.

If a form of bipolar illness had more of an environmental and less of a genetic component in its etiology, then family histories of affective illness should be less positive among "reactive" bipolar patients. We did not find this to be the case; positive family histories occurred equally often among patients who had life events and those who did not. Furthermore, when we limited affective illness in relatives to rare (and presumably inherited) forms—such as bipolar I and bipolar II illness—we did not find differences in the morbid risk for these disorders among relatives of bipolar probands who described life events and those who did not. Thompson and Hendrie (14) reported that "life-change" scores were similar for an index episode among two groups of patients with primary depressive illness (unipolar plus bipolar), one with positive and one with negative family history. Their findings support our data, although our population is more strictly defined.

Leff and associates (4) studied two rapid-cycling manic-depressives and noted life events before the initial episode but not for subsequent attacks. In contrast, we found that only about half of our rapid cyclers described life events at the onset of illness and that this percentage was similar to those who were not rapid cyclers.

In general, a higher percentage of patients reported life events before the initial episode than subsequent episodes. Our data are in agreement with the study of Okuma and Shimoyama (5) regarding this point.

The frequency of life events we found can be influenced by several factors. Although we interviewed patients to limit the time period of this study (three months before onset), it is possible that patients' recall of the relationship of the events to onset of illness may have been faulty. It should be noted that patients were usually interviewed several years after the onset of illness, although the mean ages and mean ages at onset of illness were similar for patients reporting events and those not reporting events. Furthermore, about half of another sample of patients interviewed within 2 years of onset of illness reported life events, suggesting that recall for such events might be stable over extended periods of time (D.L. Dunner, unpublished data).

Current research strategies for the study of affective illness relate to genetic-environmental interaction in the onset of symptomatology. Our data suggest that environmental stresses should be carefully evaluated in research on areas such as prospective studies of offspring of affective patients. Furthermore, since the postpartum state is clearly associated with onset of illness, we suggest that further research in postpartum depression might be helpful in determining biological factors associated with bipolar illness.

Childhood Depression: Interpersonal Interactions and Depressive Phenomena

BY IRVING PHILIPS, M.D.

The author discusses the impact of parental disability, particularly parental depression, on children. Depression in children, which takes different forms according to the child's developmental level, may mirror or be a response to similar affect in a parent. Clinicians need to take note of the relationship between child and caretaker and of the various manifestations of childhood depression in order to avoid underdiagnosing this disorder.

CHILDHOOD DEPRESSION tends to be underdiagnosed in clinical practice. Its manifestations differ from those of depression in adults. The symptoms depend on age, psychosocial development, cognitive integration, and attachment behavior. If clinicians consider the child a miniature adult and expect symptoms similar to those seen in adult depression, many children will be misdiagnosed and their problems neglected.

Childhood depression does not refer to transitory moments of sadness or disappointment but rather to frank disorder that affects development and interferes with the fullest realization of innate potential. There may be a host of etiologic factors that have not yet been differentiated and clarified. Although the biochemical factors found in adults have not been confirmed in children, they may exist as either primary or secondary features. Nevertheless, the nature and intensity of interactional factors need delineation and description. This paper will highlight interpersonal factors between parent and child that may have significance in the expression of childhood depression in ways that are congruent with the psychic and cognitive developmental level of the child.

The effects of parental behavior on child development are obvious. Parental depression interferes with the ability of a parent to best meet the needs of the child, and the result may be subsequent psychopathology in the child, in the form of depression or its equivalents.

UNAVAILABILITY OF THE ATTACHMENT FIGURE

Bowlby (1), in a classic description of attachment behavior and the consequences of separation and loss on the developing child, widened our horizons regarding the influence of normal attachment and "anxious attachment" on child development. In normal development during the first year, children form close ties with their mothers. The availability of responsive and helpful persons to the child is basic to the development of self-reliance. When such a figure is available, the individual will learn that he can deal with alarming situations and that he may seek help without hesitation, feelings of anguish, or humiliation. When attachment figures are not available enough and do not respond

enough in a warm and consistent manner, such learning may not take place, and the result is what Bowlby called anxious attachment. To quote Bowlby,

> Yet a further difficulty turns on the fact that a mother can be physically present but "emotionally" absent. What this means, of course, is that although present in body, mother may be unresponsive to her child's desire for mothering. Such unresponsiveness can be due to many conditions—depression, rejection, preoccupation with other matters—but, whatever its cause, so far as her child is concerned she is no better than half present. Then again, a mother can use threats to abandon a child as a means of disciplining him, a tactic that probably has an immeasurably greater pathogenic effect than is yet recognized. . . . Whether a child or an adult is in a state of security, anxiety, or distress, is determined in large part by the accessibility and responsiveness of his principal attachment figure. (1, p. 23)

A child confronted with such a situation goes through a typical sequence: protest, whereby he tries to recover his mother; despair, when he remains preoccupied with her and vigilant for her return; and, finally, detachment, when he becomes emotionally uninterested in her as a defense against painful feelings. The period of protest is related to his anxiety about separation, and the period of despair to grief and mourning.

Szurek (2) described mothers who were unresponsive or severely ambivalent toward their children. The earliest expressions of these children's sensual impulses were thwarted and repressed when met by the conflicted tension of the person upon whom the child depended for the satisfaction of his needs. A parent often will find it difficult to help his child experience basic needs if his own needs were frustrated during development. Thwarting of such impulses leads to frustration and inevitable rage. The child's repressed impulses undergo transformation and may express in a distorted and often caricaturized fashion the parental psychopathology that influenced the initial behavior.

Although the occurrence of depression in childhood has been debated, clinicians have recognized affective disturbance in the developing child of sufficient severity to indicate, if not frank depression, at least the precursors of adult psychopathology. Anna Freud noted,

> It was known in psychoanalysis long before such infant observations that depressive moods of the mother during the first two years after birth create in the child a tendency to depression (although this may not manifest itself until many years later). What happens is that such infants achieve their sense of unity and harmony with the depressed mother not by means of their developmental achievements but by producing the mother's mood in themselves. (3, p. 87)

Retrospective analysis has contributed to our understanding of parental loss through death or abandonment and its effects on subsequent development as well as on adult behavior. A more common occurrence is partial loss, when the caretaker, because of neuroticisms awakened by life events, cannot be emotionally available as much as he would like or as the infant needs. The parent may threaten desertion or abandonment or may shame the child sufficiently that he is afraid to seek expression of his wishes and impulses.

The varied manifestations of depression may depend on the developmental level of the child. It is obvious, as Malmquist noted, that "the response is contingent upon the child's developmental stage. The reactions to a depressed mother in an infant will vary from those in the child during the height of oedipal feelings as well as in the child during middle latency" (4, p. 956). Not only the psychic structure but also the cognitive level of the child and his ability to express painful affect by language or symbolic representations are significant. Anthony commented,

> If one accepts this close relationship between cognitive and affective development as advocated by Piaget, it would stand to reason that the experience of depression in late childhood will be radically different from the earlier experience. It is possible to go further and suggest that depression itself undergoes development throughout the child's development and that its characteristics are determined by parallel developments in symbolism, representation, language, and logical operations. The question whether depression does or does not occur during childhood, therefore, can no longer stand by itself. (5, p. 235)

CASE REPORTS

The following clinical experiences encountered in the treatment of children and families reveal incidents in which the child and a caretaker were experiencing similar affect, but which each expressed in different modes because of their different levels of psychic maturity.

Case 1. Consultation was requested at a well-baby clinic for a 17-year-old mother and her 9-month-old infant, who had failed to thrive. The mother, who was self-depreciatory and had frequent crying spells and suicidal ideas, indicated she had little time for herself or the infant. The infant was unresponsive and quite difficult to arouse. His face had a withdrawn and distant look, he was undernourished, and his growth rate was retarded.

Case 2. Bill, a 4-year-old, was abandoned by his father at birth. He was one of 3 children. His 32-year-old mother frequently spanked him (sometimes a bit too hard) to control difficult behavior. The mother's life pattern was punctuated by frequent depressive episodes; she had been hospitalized once, shortly after Bill's birth. Bill was a problem in nursery school, alternating between aggressive outbursts and hurting smaller and younger children and passively remaining by himself, refusing to enter into activities.

Case 3. George, an 8-year-old, was referred because of encopresis. When George entered the office the psychiatrist's pinched nose reflected the symptoms. George remarked, "Doctor, I have troubles. I stink inside and out." His

mother had been repeatedly hospitalized for psychotic depression since his birth, and his father was a chronic alcoholic. George was a highly intelligent youngster who was failing in school because of daydreaming and isolating behavior. His teacher remarked that she had never known a sadder youngster. When barely scolded he broke into tears.

Case 4. June, a 7-year-old, refused to go to school because of overwhelming fear. Her mother felt incapable of helping her attend. When June was 7 months old, the mother had had a severe depression that necessitated hospitalization for a 3-month period. Her father, with whom she felt unusually close, was an immature underachiever who had frequent job changes and dreams of great success that was soon to appear on the horizon.

Case 5. Jean, a 10-year-old, was devastated by the sudden death of her father when she was 9. After 2 days she rarely mentioned him again, but she wore his oversized parka wherever she went. When asked about him she responded with little emotion. Her mother, an ambitious, successful attorney, denied her grief and ambivalent feelings toward her departed husband. She lamented her new role in life. She was highly critical of her daughter, demanding high scholastic performance, a full social life, and after-school work. The daughter responded with compliant behavior but alternated between obesity and anorexia, elation and depression. Soon after the daughter entered treatment and began to rebel against her mother's unrealistic demands, the mother sought psychiatric help for herself because of progressively deteriorating behavior and severe depression.

These five examples of childhood disorder are merely paradigms of the expression of depression at various developmental levels. The symptoms of failure to thrive, passive aggression, overt sadness, school avoidance, and psychosomatic problems served to express pervasive depressive affect and clinical depression in children at different developmental levels.

DEVELOPMENTAL LEVEL AND DEPRESSIVE SYMPTOMS

At the Langley Porter Institute, University of California at San Francisco, work with each parent is part of the diagnostic evaluation of all children. The understanding of the family gained through an evaluation of both the parents and the child with the presenting complaints gives a fuller perspective on the disorder of the child. A State of California regulation required that if a parent was seen in treatment along with the child a chart be opened and a diagnosis established, and a review of the institute's records from September 1969 to December 1975 revealed 38 cases of depression in the parent and 10 cases of depression in the children, plus 1 additional report made in pediatric consultation. The relationship of these parents and the subsequent development of their children was recorded. Five of these cases were described in the previous section.

In all of these cases, the mother was the depressed parent. Eight boys and three girls were included in this series. Children with adolescent depression were not included. The predominant response to caretaker depression was passive or active aggression. The response to caretaker disability was aggression directed outward or inner passivity and withdrawal. The underlying themes seem related to efforts at compensation and expression of bereavement by whatever means was available to the child. In these cases the experiences were continuous, the bereavement unresolved, and the result was frank disorder—in these examples, depression. Although this sample is small and certainly not completely representative, it indicates that more children might be identified by clinicians if they were more aware of parental distress and its influence on the child.

In this series the clinical depression of the mother was the significant variable. In each case the history of the mother influenced her care of the child. It was evident that what she had not received in her childhood she could not give to her child, and the attachment behavior of the child was distorted.

It is likely that disorders other than parental depression may result in anxious attachment, with subsequent manifestations of depression in childhood. An increasingly frequent situation is the discharge of a mother who is heavily dosed with psychoactive drugs from a psychiatric hospital after an acute illness. Obviously this interferes with the ability of the parent to provide for optimal development of young children and interferes with their attachment behavior. The parent is not only separated from the child through hospitalization but on return finds it difficult to care for him. A variety of symptoms may result, depending on the nature of attachment between parent and child, the developmental level of the child, and intercurrent life events. A survey of phases of the growth cycle indicates various manifestations of response to interpersonal experience.

Infancy

The classic studies of Spitz (6) called attention to the institutionalized child who receives little attention from personnel, with resultant anaclitic depression. In these situations the maternal figure is not present and there are no other opportunities for attachment. The infant fails to thrive, withdraws, becomes apathetic, and in some cases dies. It became clear from a number of studies that similar affects occur in infants who remain in their own homes and fail to thrive because of maternal depression. Mothers who experience severe depression, disinterest, or apathy react to their infants in a distorted fashion. The descriptions of Fischhoff (7) and those of Fraiberg and associates (8) in the classic "Ghosts in the Nursery" emphasize this point. The infants in these studies were similar to those described by Spitz. Both caretaker and infant were depressed, each expressing the disorder through symptoms consistent with his own developmental level. Fischhoff (7) brought to our attention that deprivation may not be the only factor in failure of development and that there exists a multitude of possible factors. He noted,

> Recently Cravioto (1973) reported an ongoing study, now in its seventh year, of 300 children in a Mexican village, where malnutrition of some degree is prevalent among all the children because of "low socioeconomic and cultural backgrounds," but severe malnutrition is a "seemingly random occurrence." The investigators concluded that the development of severe "third degree" malnutrition is strongly associated with the lack of social, emotional and cognitive stimulation within the home. (7, p. 223)

The separation and resultant despair that reflect caretaker disability may be the infantile expression of depression. Szurek (2) reported that "only one child among 264 psychotic children . . . seen at Langley Porter between 1946 and 1961 was in any appreciable degree malnourished and definitely physically underdeveloped. This patient at age three years presented a picture of a severe agitated depression, restless, wringing her hands with an extremely tense facial expression and speaking little and often not at all, and showed little sign of attachment to any staff member" (p. 255). The history of the family was not presented.

A similar patient was admitted to the Langley Porter Institute children's ward. The child at age 3 was severely undernourished, refused to eat, and was cachectic in appearance. She wrung her hands so severely that she had caused tissue damage to her wrists. She refused to speak but had good eye contact. Her posture and gait were stiff and awkward. Repeated neurological examinations were within normal limits. After 3 years of residential treatment her condition had changed very little. She was below the first percentile in height and weight. Her early years had been chaotic, with her mother so constantly frightened and under threat from a paranoid husband that she had little time for her daughter. Early normal development receded into the more pathological picture described above.

Are these two examples of what may be called psychotic depression expressions of the vagaries of the depressive phenomena in infancy? It is intriguing to speculate as to whether the most severe disorders of childhood, such as the psychotic maldevelopments, may not be prototypes of severe depressive episodes occurring early in the child's development.

Preschool (2 Years-6 Years)

In the preschool period the child's language increases considerably. With cognitive development he gains the capacity for observational learning, with increased emphasis on mental representations through imitation, but he is still quite egocentric and tends toward direct action. The structuralization of his mental process becomes more formal, but the ability to think conceptually is not achieved until he moves closer to 6 or 7 years of age. He is only partially able to conceptualize ideas such as death. It is in this period that the child is vulnerable in his quest for autonomy and initiative and may identify with a depressed mother. The manifestations of depression may be varied. The reactions of children to parental disability are frequently regressive reactions—severe separation anxieties, hyperactivity, learning disorders, somatizations, and others. Depression in childhood may be best diagnosed by the analysis of the caretaker-child dyad and their reactions to each other.

School Age (6 Years-11 Years)

The beginning of operational thinking is a major turning point in the child's cognitive development. The child now learns how to organize the immediate situation in terms of a more general reality. In the structural sense, this is the time of formation of the panoply of defenses and consolidation of the superego. The loss of a parent is now understood in conceptual form, although understanding of death in the abstract sense must wait a few more years. The symptoms of depression take more nearly the form of adult depressive reaction and mirror the depression of the caretaker. The child is overly sensitive and easily hurt. Self-depreciatory feelings begin to emerge. He seeks relationships but fears them; the threat of abandonment remains in the air. Consequently, his relationships are tenuous or tentative. He vacillates between harsh self-criticism and blaming others for their faults. Observation reveals a sense of sadness and unhappiness. He may chronically complain about physical or psychological hurts. In school he may daydream or be the class clown, and for his efforts to find acceptance and reward he is scolded and sometimes punished. Seldom is he recognized as needing consolation; rather, his acting-out behavior is annoying and results in further reinforcement of his negative feelings. His suffering is unrecognized by teacher or parent, and he may go unnoticed, never receiving the attention he craves and so desperately needs. Malmquist (4), who listed symptoms of depression in middle childhood, described this type of child very well. Although the child's symptoms are more focused, they mirror those of his parent.

Finally, separation through divorce, an ever-increasing phenomenon in contemporary society, must be mentioned. The work of Wallerstein and Kelly (9) indicated the acute effects on children of such an event. Their descriptions are of depressed children, although they are not diagnosed as such. Their findings are consistent with those of clinicans who work with such families. The affect of such children is obvious and mirrors further the affects of each of the separated parents, now attempting a new life apart. In divorce the family continues, although the marriage has died.

Table 1 summarizes the disorder of depression as it appears in the developing child.

CONCLUSIONS

Childhood depression is underdiagnosed in clinical practice. There may be many factors, both biological and psychological, that contribute to its development. The role of biochemical factors has not been as clearly delineated in children as in adults. This paper has emphasized some of the psychological interactions that

TABLE 1
Developmental Chart of Childhood Depression

Age	Psychosocial	Cognitive	Mode	Symptoms	Caretaker Problems and Life Events[a]
Infancy	Trust vs. mistrust Attachment vs. "anxious" attachment	Sensorimotor phase	Autonomic nervous system Distorted ego differentiation	Anaclitic depression Failure to thrive Psychophysiologic manifestations	Parental depression Rejection Abuse-neglect (physical and psychological)

[a]Throughout all ages.

may be involved in the etiology of childhood depression. It has emphasized that parental disability, whatever its origin but especially if it is related to depression, interferes with the parent's capacity to provide the relationship needed by the child. The child, in turn, is inhibited from achieving his innate potential. A close study by the clinician of the dyad of child (with attention to his developmental level) and caretaker will increase the accuracy of diagnosis and make possible a greater understanding of the manifestations of depression in childhood.

The Psychopathology of Suicide: A Clinical Model Approach

BY JEROME A. MOTTO, M.D.

The author hypothesizes that certan types of persons at high risk for suicide constitute definable clinical models, that the process of arriving at a suicidal outcome involves elements unique to each model, and that these elements can be considered manifestations of psychopathology. This approach is investigated using two models: "Males Under Forty" and "Stable with Forced Change." The results indicate statistically reliable differences between the models in the distributions of estimated risks for persons who subsequently committed suicide compared with those who did not. The implications of the associated high-risk variables as reflections of psychopathologic processes are considered.

THE MANY factors involved in suicidal behavior call for an approach that can account for this behavior in a systematic way while considering a bewildering array of biological, social, and psychological influences. Because of this complexity, efforts to characterize the "suicide-prone person" have not produced a generally accepted formulation, although some persuasive concepts have been developed.

A large part of our dilemma involves the uniqueness of each individual; a full understanding of the suicidal impulse in a given person can only be reached by a thorough knowledge of that person. This uniqueness prevents us from readily translating our understanding into a valid generalizable principle. Further, the recognized universal characteristics of the suicidal state tend to be highly subjective processes that are often difficult to explore. The number of exceptions to specific universal elements in completed suicides is also troubling.

We are exploring a middle ground, with the hypothesis that certain kinds of people constitute clinical models in that they tend to respond to a given constellation of stresses in a similar way with regard to suicidal behavior. By defining the model and identifying the constellation of elements associated with completed suicide for that model, we may be able to reduce the disadvantages of focusing on either individual uniqueness or universal inclusiveness. Without challenging the validity of traditional psychopathologic constructs, we can acknowledge that clinical experience tells us that certain kinds of people seem to reach the suicidal act by a similar route.

If the use of models is a valid approach, the more specific the model (i.e., the more homogenous the persons involved), the more effective it should be as a predictive tool. In this report two models will be discussed, a broad one, "Males Under Forty," and a specific one, "Stable with Forced Change." The number of possible models is limited only by how subtle one wishes to be and how many subjects can be found for study and subsequent validation.

We have proceeded on the premise that identification of the person at high risk for suicide is not enough. Rather, those within the high-risk group who are most likely to complete the act must be recognized. This permits a more efficient use of treatment time and facilities when intensive efforts are needed and avoids the false sense of security that may be generated by simply screening "suicidal" from "nonsuicidal" populations.

METHOD

Subjects

Detailed psychosocial data were gathered by extensive evaluative interviews of 3,006 persons admitted to a psychiatric inpatient unit because of a depressive or suicidal state; such a population is known to be at high risk for subsequent suicide. We then determined at yearly intervals which individuals had committed suicide; the expected rate was 1%–2% per year. The dependent variable considered in this study was occurrence of suicide within 2 years of the initial evaluation. From this pool of subjects, those meeting the criteria for two models were identified and followed for 2 years.

Subjects were required to meet three criteria for inclusion under the Stable with Forced Change model: 1) rating of moderate or high on overall stability (this rating considers stability of emotional health, work, school, marriage, relationships with others, and geo-

TABLE 1
Distribution of Suicides in Index and Validation Sets of Two Clinical Models

Model	Number of Subjects	Outcome: Suicide N	Suicide %	Nonsuicide N	Nonsuicide %
Males Under Forty	858	41	4.8	817	95.2
Index set	566	27	4.8	539	95.2
Validation set	292	14	4.8	278	95.2
Stable with Forced Change	782	35	4.5	747	95.5
Index set	469	20	4.3	449	95.7
Validation set	313	15	4.8	298	95.2

graphic location), 2) absence of psychosis, and 3) a significant loss or threat of loss associated with the initial high-risk situation.

Of the 858 subjects who met the single criterion for inclusion in the Males Under Forty model, 41 (4.8%) committed suicide during the follow-up period. Of the 782 subjects who met the three criteria for the Stable with Forced Change model, 35 (4.5%) committed suicide during the follow-up period.

Index and Validation Sets

Subjects satisfying the criteria for each model were divided randomly into an index set and a validation set, with the constraint that the validation set include at least 14 suicides (a figure determined by statistical methods to be necessary for validation purposes). The final breakdown is shown in table 1.

Variable Screening

For the two index sets, 183 psychological and social variables elicited in the initial interview were examined for their individual association with the outcome variable, suicide within 2 years. The procedures used have been previously outlined in detail by Heilbron and Bostrom (1). This screening process identified 64 variables in the Males Under Forty model and 46 variables in the Stable with Forced Change model that showed a significant association ($p<.05$) with suicidal outcome.

Model Development

The variables selected in the screening process were entered into a stepwise linear discriminant analysis. The resulting discriminant functions contained 13 variables for the Males Under Forty model and 11 variables for the Stable with Forced Change model.

The variables selected by the discriminant analysis were then analyzed in a series of linear logistic regressions, in which the estimated values of p can be interpreted as estimates of risk of suicide within 2 years. After fitting a logistic model, the variable with the weakest coefficient was eliminated and the model fitted again until all remaining coefficients were significant at the .05 level. For the Males Under Forty model 1 variable was eliminated in this way, leaving a total of 12, while 2 variables were eliminated from the Stable with Forced Change model, leaving a total of 9.

TABLE 2
Predictor Variables for Males Under Forty Model

Variable	High-Risk Factors	Number of Subjects	Suicides N	Suicides %	p
Marital status	Divorced or separated[a]	64	7	10.9	<.02
Residence	Hotel, small[a] or medium[a]	79	8	10.1	<.02
Occupation	Higher executive[a] or semi-skilled	129	12	9.3	<.01
Help sought after attempt	Actively sought help	74	7	9.5	<.05
Seriousness of injury from attempt	Required intensive care	72	9	12.3	<.01
Living arrangement	With nonfamily mixed group/ opposite sex	88	9	10.2	<.02
Stress, other	Severe	174	13	7.5	<.04
From broken home	Death of father or divorce with mother departed	68	9	13.2	<.005
Emotional disorder in family	Alcoholism	121	11	9.1	<.02

Degree of psychosis	Moderate or severe[a]	124	11	8.9	<.02
Degree of religious activity	Low or moderate[a]	105	10	9.5	<.02

[a]Number of observations too few to be reliable unless pooled with other indicated categories.

RESULTS

Variables Associated with High Risk and Suicide

The characteristics most clearly associated with high-risk subjects in the index set of the broad Males Under Forty model who committed suicide within 2 years are indicated in table 2. The characteristics associated with suicide in the high-risk subjects in the index set of the more specific Stable with Forced Change model are indicated in table 3.

Three variables are common to both models: marital status, occupation, and seriousness of injury during the present suicide attempt. With the exception of one category of marital status (separated), which contained only 2 persons in one model and 1 in the other, the high- and low-risk category groupings are identical in the two models for these 3 common variables. The weighting of marital status is approximately the same for both models, while the Stable with Forced Change model gives a slightly greater weight to the high-risk occupational categories and the Males Under Forty model gives greater weight to the high-risk category of seriousness of injury from present attempt.

TABLE 3
Predictor Variables for the Stable with Forced Change Model

Variables	High-Risk Factors	Number of Subjects	Suicides N	Suicides %	p
Marital status	Divorced	78	7	9.0	<.04
Religious affiliation	Protestant, Jewish,[a] Fundamentalist,[a] other,[a] or no affiliation	312	18	5.8	<.02
Occupation	Higher executive[a] or semi-skilled[a]	76	8	10.5	<.01
Last change in occupation	Within 1 month[a] or no change	262	17	6.5	<.01
Seriousness of injury from attempt	Required intensive care	88	8	9.1	<.02
Severe loss other than significant person	Any but academic loss	209	17	8.1	<.001
Physical health in past year	Severe disability[a] or progressively worse	165	13	7.9	<.01
Crying during present illness	None or unable to cry	159	12	8.1	<.01
Personality pattern	Obsessive or schizoid	126	12	9.5	<.002

[a]Number of observations too few to be reliable unless pooled with other category or categories.

TABLE 4
Median Estimated Risk of Suicide Assigned to Subjects Who Did or Did Not Commit Suicide

Model	Risk: Nonsuicide	Risk: Suicide	p	Separation Index[a]
Males Under Forty				
Index set	.0078	.2448	<.0001	.926
Validation set	.0082	.0221	<.04	.661
Stable with Forced Change				
Index set	.0056	.2752	<.0001	.932
Validation set	.0056	.0288	<.01	.705

[a]The separation index, which reflects the separation of risk distributions for subjects who committed suicide and those who did not, is the proportion of suicide/nonsuicide pairs in which the suicide had a higher estimated risk.

Performance of the Models

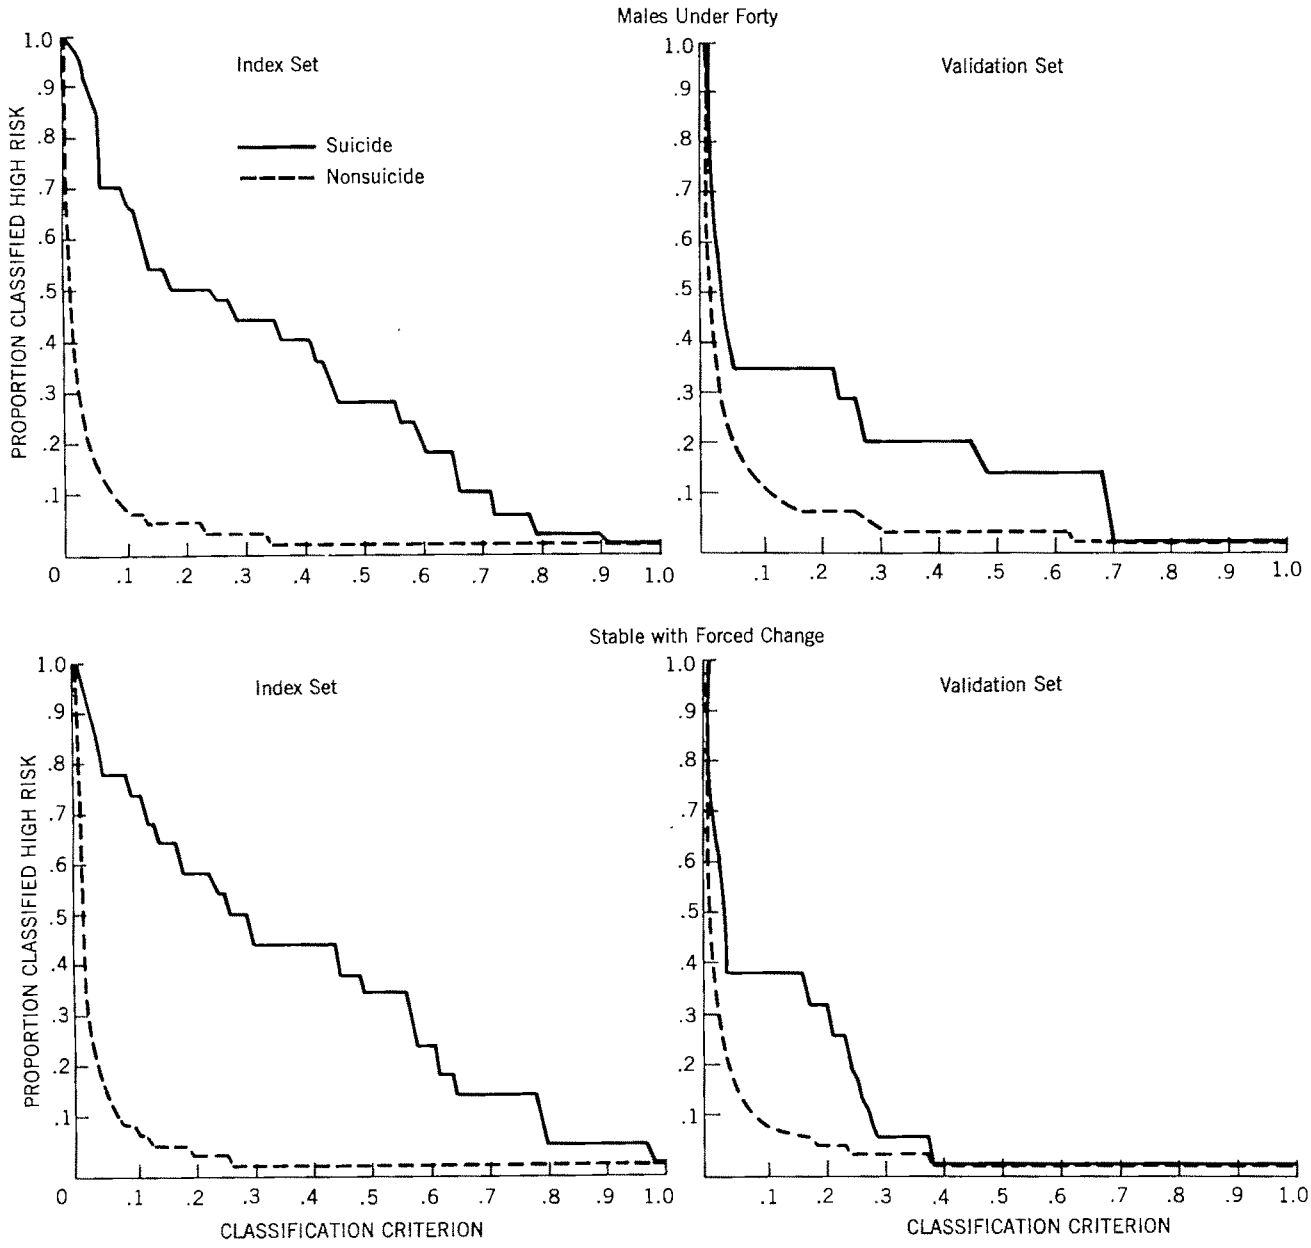
The estimated risk of suicide can be compared with the actual suicidal outcome by showing that persons who subsequently committed suicide were assigned higher estimated risks than those who did not. The median estimated risks and the Mann-Whitney chi-square statistics for testing differences in these medians are shown in table 4. In addition, the proportion of suicide/nonsuicide pairs in which the suicide had the higher estimated risk is a related measure of the separation of the two distributions of risks; this proportion is indicated in the last column of table 4. This figure would be .50 if estimated risks did not, in general, differ between suicides and nonsuicides. Perfect separation would yield a value of 1.00. As postulated above, the more precise model (Stable with Forced Change) provides a clearer separation of the suicides and nonsuicides than the less precise one. Especially gratifying is the small proportion of nonsuicides (6%) who were classified as high risk under this model.

TABLE 5
Identification of Actual Suicides and Nonsuicides Using Optimal Criterion for High Risk

Outcome	Index Set: High Risk N	Index Set: High Risk %	Index Set: Not High Risk N	Index Set: Not High Risk %	Validation Set: High Risk N	Validation Set: High Risk %	Validation Set: Not High Risk N	Validation Set: Not High Risk %
Males Under Forty								
Suicide	25	93	2	7	9	64	5	36
Nonsuicide	99	18	440	82	94	34	184	66
Stable With Forced Change								
Suicide	15	75	5	25	6	40	9	60
Nonsuicide	36	8	413	92	18	6	280	94

All indices show a decrement between index and validation sets, as expected. However, the data for both models on the validation sets indicate real, statistically reliable differences in the distributions of estimated risks for those who subsequently committed suicide compared with those who did not.

Figure 1 shows the cumulative distributions of estimated risks for suicides and nonsuicides in the index and validation sets for each model. These are plotted to show how setting an arbitrary criterion for classifying a person as high risk affects the proportion of actual suicides and nonsuicides so classified. As this criterion is lowered (moved left on the scale), a progressively larger proportion of the actual suicides is identified, at the expense of increasing the proportion of nonsuicides also classified as high risk.



The point at which the two curves are most separated indicates the criterion value (or cutoff point for high risk) that yields the fewest total false positives and false negatives. Using this optimum criterion provides identification of actual suicides and nonsuicides compared with their estimate of risk, as indicated in table 5.

DISCUSSION

To use clinical models in studying the psychopathology of suicide is to acknowledge that, whatever the process leading to the suicidal act, high-risk persons who demonstrate a specific clinical pattern (model) appear to share observable indicators of the likelihood of suicide. These indicators can be construed as reflecting crucial intrapsychic processes that may respond to clinical intervention and—what is most important here—that will differ with different models.

This relationship of quantifiable data to underlying psychopathology can be seen as a function of the preciseness of the model. An age/sex-specific group such

FIGURE 1
Cumulative Distribution of Estimated Risk for Index and Validation Sets of Males Under Forty and Stable with Forced Change Models

as Males Under Forty allows for so varied a representation that the relationship can hardly be very close. As the model becomes more detailed, however, we can anticipate a progressively more direct translation of the correlates of high suicide risk into implications for psychopathology.

In the present instance, we can postulate that persons with relatively stable life patterns tend to exert a certain control over events in their life as a way of maintaining that stability. The capacity for control becomes a key dynamic in their adjustment and may be manifest clinically as obsessive personality traits. However, although crying may be controlled, events such as progressive worsening of physical health may not. A change in occupation can be necessitated by economic conditions, a spouse may leave, or an intercurrent stress be sustained. Without the support of spouse, colleagues, or strong religious affiliation, a suicidal state with a fatal outcome is highly probable. Although other persons who fit the Stable with Forced Change model may go through suicidal periods under stress, if they do not fall into the high-risk categories indicated their level of risk will be significantly lower. On the other hand, the presence of these high-risk factors may have relatively little significance in persons who do not fit the Stable with Forced Change model.

Applying this concept to the less precise Males Under Forty model necessarily involves a less direct translation of the correlates of high risk into intrapsychic process, as mentioned above. In this instance we can postulate that the presence of alcoholism in the family would be conducive to generating anxiety and instability of object relations, which are compounded if the family breaks up. This breakup would be especially handicapping emotionally for the young male if it occurred through the death of an alcoholic father because in this case the still unresolved process of identification and dependent-independent conflict with ambivalence toward the parent of the same sex is involved.

Continued instability is manifest in adult life in the form of marital conflict, transient forms of residence and living relationships, and significant thought disorder. When intercurrent stresses occur in the absence of a cohesive family or other support system, suicide may seem to be the only alternative. The still-unresolved dependent-independent struggle is seen in the person's behavior following serious attempts.

Such a formulation, based on the high-risk variables listed in tables 2 and 3, may seem to lean heavily on "psychologizing," but experienced clinicians and suicide prevention workers will recognize familiar markers at each step. Individual differences must still be considered in therapeutic efforts, of course, but those efforts can be more efficient if they are concentrated on persons in the 5%–6% per year fatality range than on those in the 1%–2% group. To date, the only demonstrated and validated means of objectively identifying such a high-risk population is by starting with models such as those discussed here. Earlier efforts to accomplish this task (2–5) contributed greatly to the development of the model concept, but they were limited by small sample size, retrospective design, or lack of validation.

An encouraging finding in the present study is the relatively small overlap of the high-risk variables applicable to the two models examined. This supports the hypothesis that the subgroups do represent different clinical entities that can be studied with a view toward developing treatment approaches most effective for each. Comparing the high- and low-risk categories for each variable in each model with the corresponding categories of the subjects in the other model, 11 are found to be in the same direction of risk and 10 in the opposite direction, giving further support to the independence of the two models.

In view of the poor results of rigorous validation efforts in the past (6), the performance of the predictor variables in the validation sets is most encouraging. This is especially so in view of the reduction of the variables to a number (12 for Males Under Forty, 9 for Stable with Forced Change) that can be applied easily in most clinical settings.

One source of ambiguity is the inevitable need for "other" categories in gathering data. In this study it was applied to religious affiliation to indicate membership in religious groups that are minorities in the United States, such as Mormon, Moslem, or Greek Orthodox churches. In reference to "loss" or "stress" the "other" category included an array of situations that defy classification, such as relinquishing a cherished goal, learning one is infertile, sale of a family home, an amputation, facing military draft, or loss of a feeling of independence or respectability. These stresses are pertinent to suicidal individuals but are difficult to apply generally to a high-risk population.

It remains to develop a variety of additional models in order to include the bulk of very high-risk persons in this approach. Although study of the many theoretic and clinical aspects of self-destructive behavior will never be an exact science, we are encouraged to believe that it is still possible to supplement the clinical and intuitive skills of health workers to minimize the number of unnecessary, premature, and tragic deaths from this cause.

Depression Simulating Organic Brain Disease

BY JESSE O. CAVENAR, JR., M.D., ALLAN A. MALTBIE, M.D., AND LINDA AUSTIN, M.D.

The authors report four cases of depression manifesting as organic brain syndrome in adult nongeriatric patients. The correct diagnoses in three cases were made by a psychiatrist's or resident's empathic response to the patient, and in the fourth by the patient's history of depression. The authors state that only by maintaining a high degree of suspicion and trusting one's empathic response to the patient will unusual presentation of depression be recognized.

VERWOERDT (1) NOTED that depression in senescence is commonly overlooked because it does not always follow the same pattern or have the same symptoms as in the younger age group. The affective manifestations of depression, such as sadness, crying spells, guilt, and self-depreciation, may be absent. Impairment of memory, somatic symptoms, psychomotor retardation, and loss of initiative may be the more prominent symptoms and may be confused with an organic brain syndrome.

Although most gerontologists agree that depressive disorders in older patients may have an atypical clinical picture, this phenomenon has not been reported in younger patients. In fact, most authors suggest that it is not seen clinically. Cohen (2), in describing the depressive type of manic-depressive illness, stated, "There is no disorientation" (p. 683). Ford (3) noted that in involutional depressive reactions "the sensorium is clear" (p. 701).

The purpose of this communication is to report our experience with an unusual manifestation of depressive disorders in adult nongeriatric patients. Our work suggests that in certain patients a severe depressive disorder may have the clinical features of an organic brain syndrome and lack the usual depressive signs or symptoms. Our experience is illustrated by the following cases.

CASE REPORTS

Case 1. Mr. A was a 50-year-old blue collar worker who was brought for emergency psychiatric evaluation by his wife. Over three months he had displayed increasingly bizarre behavior to the extent that he was rummaging through neighbors' garbage cans, refusing to go to work, and grossly confused as to time and place. His family noted that his disorientation seemed more pronounced at night. To the family's knowledge, his past physical health had been good and he had not been consuming alcohol.

Mr. A had been taken to his family physician several days before the emergency evaluation. This physician suspected that the patient had a brain neoplasm, but a thorough physical workup, including skull radiographs, neurological examination, and brain scan, were negative or normal. A mental health professional had evaluated the patient and had told the family that Mr. A had a severe organic brain syndrome and recommended institutional care.

The mental status examination revealed a dirty, unkempt man who appeared older than his stated age. He was grossly confused to time and place. His recent memory seemed impaired; he could not name the President or his own date of birth. His affect seemed to be one of bewilderment but was not depressed. The family reported that he had not seemed sad or depressed, slept well during the day, had had no crying spells, and had a good appetite.

Despite this seemingly clear organic picture and an absence of any signs of depression, the examining psychiatrist (J.C.), who is a psychoanalyst, believed the patient was depressed. Countertransference caused the psychiatrist to feel sad and many depressing thoughts came to his mind.

Amitriptyline was prescribed in therapeutic doses, and an appointment was scheduled for the following week. Mr. A came for that appointment neatly dressed and groomed; he reported that he had begun to sleep at night after taking the medication and that he was now "thinking clearly." He was oriented to time and place. His recent and remote memory were intact; his intelligence was estimated to be above average. His mood was normal. He showed no thought disorder and denied hallucinations or delusions. Mr. A's family confirmed that he was improved. He was seen on three subsequent visits and continued to appear completely recovered. Despite the fact that he was cautioned that he needed to continue the medication for six months, he neglected to return because he felt so well. He was subsequently lost to follow-up.

Fifteen months later Mr. A, accompanied by his family, appeared as a psychiatric emergency. He had again experienced increasing confusion over a period of several months and was grossly disoriented. He was dirty, unkempt, and to-

0002-953X/79/05/0521/03/$00.40 © 1979 American Psychiatric Association

tally disoriented to time and place but had no observable depressive signs. His family denied that any depressive symptoms had been present.

Mr. A was again treated with amitriptyline and seen one week later in follow-up. At that time he was well dressed, well groomed, and totally oriented to time and place. His cognitive function appeared to be intact, and his mood was normal. He remained well over the following seven months until he was again lost to follow-up.

This man appeared to have a classic organic brain syndrome characterized by confusion, disorientation to time and place, and memory disturbances. It was only through an empathic response in the examiner that depression was suspected; there were no signs or symptoms of depressive illness. No precipitating event was ever identified that might have led to the onset of the depression.

Case 2. Ms. B was a 22-year-old housewife who was seen as an emergency case because of confusion and disorientation. She had a six-month-old baby and had had an uneventful pregnancy and delivery. Two months before admission she had complained of "not thinking clearly." This had gradually worsened to the point where she was grossly confused and disoriented.

Her husband denied that she had experienced any anorexia, weight loss, crying spells, or sadness. She had been "restless" at night but had not had any significant sleep disturbance. Most disturbing was her disorientation in the evening and nighttime hours.

The mental status examination revealed that Ms. B was confused and disoriented. She did not appear to be depressed and specifically denied any sleep disturbance, weight loss, sadness, crying spells, or suicidal ideation. No delusions were noted and she did not appear to be hallucinating.

Ms. B had been seen by her family physician before psychiatric referral. A physical examination, neurological examination, brain scan, electroencephalogram, and skull radiographs were all negative or normal. She had not been febrile.

Ms. B seemed to be depressed, notwithstanding the fact that she denied any depressive symptoms and did not look depressed. The impression of depression was suggested by the fact that the psychiatrist found himself feeling dejected and blue after several minutes of talking with her. He prescribed therapeutic levels of amitriptyline.

When evaluated the following week, Ms. B appeared much better. She was oriented to time, place, and person and did not appear to be psychotic. She had some difficulty in recalling recent events and, particularly, names, but this was much less pronounced than it had been. Her medication dosage was increased and she was given an appointment for the following week.

At that appointment Ms. B's husband reported that she was "back to herself" in every way. She seemed totally oriented and demonstrated no memory deficits. She was outgoing, pleasant, and cheerful and showed no signs of psychopathology.

Ms. B's amitriptyline dosage was maintained and she was seen monthly for brief office visits over four months. Her family moved to another city at that time and contact with her was lost. However, during that time no other confusional episodes were noted.

Again, the examiner's countertransference and empathic response was significant in suggesting the proper diagnosis for this patient.

Case 3. Mr. C was a 51-year-old man who was hospitalized in September 1976 after a myocardial infarction. He made an uneventful recovery from the infarction but appeared depressed to the cardiologist. The cardiologist did not request psychiatric assistance, however, because the depression did not seem severe.

Mr. C requested psychiatric evaluation in February 1977 because of decreased energy and difficulty falling asleep at night. He denied depressive symptoms and had an excellent appetite.

Mr. C was a small, neatly dressed, pleasant, and cooperative man, who appeared 10 years older than his stated age. His speech was slow and halting, he performed mathematical calculations extremely poorly, and he quickly lost track of the task. There was no evidence of thought disorder, and he was not psychotic. His affect was labile and alternated between smiling appropriately and crying.

The patient was admitted to the psychiatry service for evaluation. Psychological testing for organic brain syndrome failed to show any organic central nervous system damage. An electroencephalogram was normal, as was the neurological examination. Mr. C appeared confused on the ward.

Antidepressant medication in therapeutic levels was begun because it was believed that Mr. C had a depressive disorder appearing as an organic brain syndrome. As Mr. C improved, he began to talk of his 22-year-old daughter who had died suddenly of anaphylactic shock in April 1976; his ambivalent feelings about her were the source of his depression. This information was not available, however, until Mr. C had improved to the point that he could communicate it to his physician. Most interesting was the fact that as the depression improved, the confusion cleared in direct proportion. The best clinical indicator of the extent of depression was Mr. C's ability to do serial subtractions of 7 from 100. At the end of a 6-week hospitalization, Mr. C could do mental arithmetic quickly and accurately. His lability of affect, confusion, staggering gait, and poor articulation all cleared as the depression improved.

Case 4. Mr. D was a 48-year-old disabled man who had been transferred from a chronic care psychiatric hospital where he had been hospitalized for over a year with the diagnosis of organic brain syndrome. Progressive confusion, memory loss, loss of energy, and his family's inability to care for him had led to the hospitalization. A thorough evaluation had been done, and there were no abnormal findings on the skull radiographs, brain scan, or electroencephalogram.

When evaluated upon transfer, Mr. D appeared to have a chronic organic brain syndrome. There was nothing on the mental status examination to suggest any depressive or psychotic disorder. An air of pessimism among the ward staff and psychiatrists was obvious; it appeared that nothing could be done.

Fortunately, a psychiatry resident in the first month of training started the patient on antidepressant medication. The resident could offer no objective reason or rationale as to why the medication was started; the patient's "organic brain syndrome" began improving, and within three months he completely recovered and was discharged.

Verwoerdt (1) noted, "All too often, an elderly patient who is essentially depressed receives the diagnosis of organic brain syndrome, after admission to the hospital, and then is treated accordingly. The result is that the patient begins to conform to the attitudes of his environment; i.e., he will start behaving more and more like a senile patient" (p. 46). Al-

though our patient was only 48 years old, it appeared that this was exactly what had happened.

DISCUSSION

The concept of a depressive disorder manifesting as an organic brain syndrome in young adult and middle-aged patients is vitally important to the clinician. As illustrated by the previous case reports, these patients may not experience the typical depressive symptoms.

The first two cases were diagnosed primarily by the psychiatrist's empathic and countertransference response to the respective patients. Kernberg (4) noted that countertransference may include the examiner's conscious and unconscious reactions to the patient and to the patient's reality situation; he suggested that countertransference is useful in understanding the patient. Kernberg stated that patients with borderline and psychotic levels of organization tend "by their intense, premature, and rapidly fluctuating transference, to evoke intense countertransference in the therapist which may at times give the most meaningful understanding" (p. 40). We believe that this is the situation in those patients who are depressed but appear to have an organic brain syndrome.

Mr. C's depression was diagnosed because of his history of depression. This would seem to suggest that the history of depressive disorder is vitally important to ascertain and may in fact be the only clue that a depression is present when the patient appears to have an organic brain syndrome.

In only one case were we able to elicit any material that might have led to a diagnosis of depression; this information was not available until after the patient (Mr. C) began to improve to the point where he could, or would, verbalize his concerns. The lack of losses or life circumstances that would tend to lead one to suspect a depressive disorder, plus the rapidity of response to antidepressant medication in the first two cases, suggests to us that depression was probably a biological phenomenon in these patients.

Mr. D's case is unusual in that a resident physician who was new to the field of psychiatry experienced an empathic response to the patient's depression; failing to realize that antidepressants are not indicated in organic brain syndromes, the resident's actions led to the proper treatment of the patient with subsequent recovery.

It is only through a high index of suspicion and one's empathic response to the patient that this unusual presentation of depressive disorders will be recognized. Because depressive illness is treatable and has a good prognosis, it is essential that it be differentiated from the organic brain syndromes. One can only wonder how many patients have been diagnosed as having organic brain syndrome and hospitalized for chronic care when in fact they are depressed, as was Mr. D.

Depression in the Wives of Nuclear Submarine Personnel

BY KAREN BECKMAN, ANTHONY J. MARSELLA, PH.D., AND RUTH FINNEY, PH.D.

The authors compared levels of depression among 24 wives of nuclear submarine personnel under conditions of husband-presence and husband-absence in a crossover research design. The wives had significantly higher depression scores under conditions of husband-absence on both the Zung Depression Scale and the Multiple Affect Adjective Checklist. The results are discussed in terms of the tremendous stresses imposed on the wives as a result of the nuclear submarine deployment schedule and the failure of the Navy and the spouses to recognize and reward the wives for their efforts.

UNLIKE PERSONNEL in other branches of the military service, nuclear submarine personnel in the U.S. Navy Fleet Ballistic Missile program typically serve in 3-month rotational cycles; i.e., 3 months at sea, 3 months at home. This cycle is often continued through the entire tour of duty. For the wives of nuclear submarine personnel, this particular service pattern poses a severe stress. It requires a constantly shifting role pattern. During the husband's absence the wife often has complete responsibility for home and family; when the husband returns this role generally shifts back to him. In addition, the wife is faced with a repetitive grief response whenever the husband leaves.

For many submarine wives the difficulties of these two situations are exacerbated by the absence of any institutional resources for coping with the problems. Although counseling facilities are frequently available, the wife seeking help may be labeled "dependent" or "weak" by other wives, her husband's superiors, or even her own husband. The wife is faced with the omnipresent pressure to be a "good military wife"—to sacrifice for the good of her husband's career. However, even among those wives (and there are many) who are willing to fulfill the traditional military wife's role of accepting the burdens of military life, there are few supports. Thus both the resentful wife and the "good military wife" are often forced to keep their feelings regarding the role conflicts and the normal grief reactions to themselves.

Previous publications (1-3) have commented on the problems of the military family. Of special importance is the observation by Frances and Gale (1) that the stress of military life may frequently cause the nuclear family members to become more dependent on each other. What happens, then, when the family separates, as is the case with nuclear submarine personnel? A loss of support can precipitate depressive emotional states. In addition, the separation can signal the forthcoming stress from the additional responsibility and role conflict that the wife will probably experience as she assumes her husband's tasks and obligations (see references 4 and 5 for discussions of role problems among women).

Bermudes, a chaplain, noted that many wives of nuclear submarine personnel came to him with symptoms similar to those of his parishioners who had lost a husband through death (6). He administered a questionnaire to these women and found that the wives evidenced a distinct behavior pattern of "emotional highs and lows similar to the grief responses ordinarily observed in one who has lost a loved one through death" (p. 218). Bermudes identified five stages in the grief response. The last stage was one of despair and despondency.

The purpose of the present research was to examine the adjustment response of the wives of nuclear submarine personnel through an investigation of depression levels under conditions of husband-presence and husband-absence. It was hypothesized that the wives would score significantly higher on depression measures under the condition of husband-absence. The basic research strategy employed was a crossover design to control for possible order effects.

METHOD

Subjects

The sample consisted of 24 wives of nuclear submarine personnel. The mean age of the subjects was 26.3 years, and the mean number of years married was 6.1. The subjects' education level was 12.9 years. They had a mean of 1.6 children each, and the mean age of their spouses was 28.3 years. They were of the same socioeconomic level (only a few were married to

The authors wish to express their deep gratitude to the wives who participated in this study.

0002-953X/79/05/0524/03/$00.40 © 1979 American Psychiatric Association

junior-grade officers; the majority were wives of noncommissioned officers). The subjects had lived in Hawaii for an average of 2.2 years, enough for a minimum of 4 sea-duty tours.

Procedure

The subjects completed 2 measures of depression: the Zung Depression Scale (7) and the Multiple Affect Adjective Checklist (MAACL) (8). These 2 measures were selected because they assess depression by different formats. The Zung scale uses a symptom frequency format, while the MAACL uses a mood adjective checklist. Thus it was believed that the 2 measures would cross-validate one another (9).

The depression measures were administered to 14 subjects whose husbands were on sea duty and to 10 subjects whose husbands were at home. During the next duty cycle the depression measures were readministered to the 14 subjects whose husbands were not on sea duty and the 10 subjects whose husbands were not at home. This type of research design permitted the subjects to serve as their own control for the comparison of levels of depression during both conditions. All measures were administered during the fifth week of the sea duty—home leave cycle. There were no marked differences between the 2 groups in age, education, number of children, or number of years married.

RESULTS

During the first 3-month cycle the wives whose husbands were absent had a mean Zung Depression Scale score of 54.29, while those whose husbands were present had a mean score of 38.50 ($t=3.61$, $df=23$, $p<.001$, t test for independent samples). The wives whose husbands were absent had a mean MAACL score of 15.71, while those whose husbands were present had a mean score of 8.50 ($t=2.52$, $df=23$, $p<.009$, t test for independent samples).

During the second 3-month cycle, in which the conditions were reversed, the wives whose husbands were then present had a mean Zung Depression Scale score of 46.43, while those whose husbands were absent had a mean score of 51.00 ($t=3.08$, $df=23$, $p<.003$). The wives whose husbands were present had a mean MAACL score of 10.21, while those whose husbands were not at home had a mean score of 16.40 ($t=3.29$, $df=23$, $p<.003$). Thus on both measures of depression the wives earned significantly higher scores under conditions of husband-absence.

To compare each subject's score under conditions of husband-presence and husband-absence regardless of the cycle, a t test for correlated samples was used. The mean score on the Zung Depression Scale for all of the subjects under conditions of husband-presence was 43.13, compared with a mean score of 52.92 under conditions of husband-absence ($t=3.51$, $df=23$, $p<.002$). According to Zung scale norms, the latter score suggests the presence of clinical levels of depression. A similar analysis of the MAACL scores for the 24 wives indicated that they had a mean score of 9.50 under conditions of husband-presence and a mean score of 16.00 under conditions of husband-absence ($t=4.26$, $df=23$, $p<.001$). Thus the scores on the different depression measures corroborated one another.

DISCUSSION

The results of this study provide an empirical demonstration of the development of clinical levels of depression among wives of nuclear submarine personnel during the course of their husbands' 3-month absence for sea duty. The depression was extremely responsive to the presence or absence of the husband; in this respect it appears to resemble strongly the grief reaction described by Bermudes (6) and Kübler-Ross (10). Bermudes concluded that there are 5 stages in the grief reaction. Interviews with the wives after the completion of testing revealed anecdotal support for this theory.

The wives reported that they started to withdraw from their husbands weeks before their departure (stage 1—shock). They often argued with their spouses over little things that had no bearing on their leaving. They also lost their patience with their children (stage 2—emotional release). When the husbands left, the wives reported that they withdrew. One wife said that she did not talk to her neighbors during this period because "they seemed silly." All of the wives stated that they felt an added burden of responsibility for the children and the home during their husbands' absence (stage 3—withdrawal). They also noted that they lost their tempers easily. Further, they became angry and resented the Navy (stage 4—anger). Eventually, they felt depressed and cried or slept much of the time (stage 5—depression).

Yet, through all of these cycles, which are repeated again and again in the course of a 4-year hitch (the careerman may keep up these cycles for several hitches), the wife survives, often without any support or recognition from the Navy. She takes care of the home and the children. She goes to work and tries to maintain the image of a "good military wife." She fears that her husband will not love her when he returns, that he will not approve of how she has managed things, and even that she may not love him as much.

The strain of the nuclear submarine service on the wife is great. The Navy should give careful attention to this type of deployment service because of its risks. There is truth behind the adage, "They also serve who only stand and wait." As one wife stated, "I can take all of this. I can even grow as a result of being on my own with all the responsibility. But, just once, . . . just once I would like some recognition for the support I do give to the Navy . . . and perhaps some recognition for being one hell of a woman to put up with this [kind of life]."

Depression in Viet Nam Veterans and Civilian Controls

BY JOHN E. HELZER, M.D., LEE N. ROBINS, PH.D., ERIC WISH, PH.D., AND MICHI HESSELBROCK, M.S.W.

In order to investigate the long-term psychological consequences of Viet Nam combat, the authors located and personally interviewed a group of 571 randomly selected Viet Nam veterans and 284 matched civilian controls 3 years after the veterans returned to the United States. In the veterans they found a weak association between combat and subsequent depressive symptoms, but the association did not persist after controlling for preservice factors. The incidence of depressive symptoms and syndromes was similar when veterans were compared with nonveterans. Results are contrasted with a 12-month follow-up study of the same veterans in which a stronger association between combat and later depression was found.

IN A PREVIOUS publication (1) we discussed the occurrence of depressive syndromes in a group of Viet Nam veterans after their return to the United States. We found that postwar depression occurred significantly more often in men who had been exposed to combat in Viet Nam than in noncombatants. This relationship persisted after controlling for other relevant preservice and inservice variables.

The first follow-up investigation of our veterans sample was conducted 8 to 12 months after their return to the United States. We have now completed a second follow-up of this same group of veterans 3 years after their return and have interviewed a matched control group of nonveterans for comparison. In this second follow-up report, we will compare the occurrence of depressive symptoms in veterans and nonveterans in the 2 years prior to interview and examine the association of military combat with subsequent depressive syndromes.

METHOD

Approximately 13,760 U.S. Army enlisted men returned to the United States from Viet Nam in September 1971. With the assistance of the military, we selected a sample of 943 men for follow-up study. The sample was divided about evenly into two groups: 1) 470 subjects randomly chosen from all returnees, and 2) 495 subjects randomly selected from a group of men who had been identified as illicit drug users on the basis of a urine screening test at the time of departure from Viet Nam. There was an overlap of 22 men. The subjects were located and personally interviewed 8 to

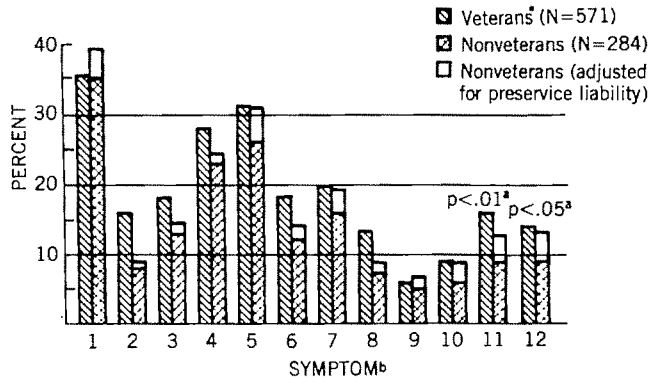
12 months after their return to the United States. In our previous study of postcombat depression, we used the data from the 470 "general sample" men only (1).

At the time of the second follow-up, 3 years after return, we reduced the size of the veteran sample by eliminating men from the least populous states and those inducted before 1969. This enabled us to select and examine a matched nonveteran control group. In order to maintain an adequate sample size of veterans, we combined data from the drug-positive and general samples for this second analysis. To avoid biasing the general sample with large numbers of men who used illicit drugs heavily in Viet Nam, we weighted the drug-positive sample to represent its true proportion in the general sample. There were 605 men in this combined veterans sample. We were able to locate and interview 571 or 94%.



With the help of the Selective Service System, we identified 302 men who were matched to the general sample veterans on the basis of draft eligibility, size and location of predraft residential area, age, and education at the time of the veteran's entry into the military. These were all men who were eligible to serve in the military but did not, either because their lottery numbers were not drawn or they obtained deferments. We located and interviewed 284 (94%) of the controls.

At the first follow-up, we had inquired about depressive symptoms occurring at any time during the 8- to 12-month period since the veteran's return to the States. We did not investigate whether these symptoms occurred simultaneously, because the total interval was fairly brief. The second follow-up interview, covering a 2-year period, made this distinction. The definition of a depressive syndrome for the present study is dysphoria for at least 1 month, occurring at any time during the 2-year period since the first interview, and three or more simultaneous depressive symptoms among those shown in figure 1.

We defined combat in Viet Nam as positive responses to two or more of the three following interview items regarding combat experiences: 1) Did you go on combat patrols or have other very dangerous duty? 2) Were you ever under enemy fire? 3) Were you ever surrounded by the enemy? This also differs from the definition used in the first follow-up study in which combat was defined as a positive response to only the first of these three items. To test the validity of our current definition of combat, we examined two of its correlates. Veterans who met our definition of combat were 50 times more likely to have had friends killed in combat and 90 times more likely to have been wounded.

In the following analysis, we will compare veterans to nonveterans in terms of frequency of depressive symptoms and the depressive syndrome in years 2 and 3 since the veterans' return from Viet Nam. We will also examine whether combat contributes to any excess of depression among the veterans. Since we are interested in isolating the effect of combat as an antecedent stressful event, we will remove from our analysis men who were wounded in combat since physical injuries may profoundly influence psychological adjustment.

FIGURE 1
Depressive Symptoms Over a Two-Year Period

[a]Differences are significant only before adjusting for preservice differences.
[b]1=dysphoria at least 1 month; 2=insomnia; 3=anorexia and weight loss (8 lbs.); 4=loss of energy; 5=loss of interest; 6=feelings of guilt; 7=poor concentration; 8=worry about insanity; 9=crying spells; 10=thoughts of death or self-harm; 11=depressive syndrome; 12=depressive syndrome excluding 77 wounded veterans.

RESULTS

In figure 1, the cross-hatched bars show the frequency of depressive symptoms occurring over a 2-year period in all of the interviewed veterans and nonveterans. With the exception of dysphoric mood, which was equal for the two groups, substantially higher proportions of veterans reported each of the depressive symptoms, and several of these differences are statistically significant. More of the veterans met our criteria for a depressive syndrome occurring at some time during the 2-year follow-up (χ^2, $p<.01$). The difference in depressive syndrome continues to be significant after excluding the veterans who were wounded in Viet Nam ($p<.05$).

Despite our matching procedure, there were distinct differences between veterans and nonveterans for certain preservice variables such as antisocial behavior and drug use. Since many of these preservice factors were found to be powerful predictors of social adjustment and depressive symptoms after return from Viet Nam, it was obviously necessary to control for these before we could attribute postservice differences to Viet Nam or to the military experience. We constructed a preservice liability scale consisting of demographic descriptors, deviant behavior, and drug use (2). We then controlled for differences in preservice liability in the veterans and nonveterans by using an epidemiological method known as direct standardization (3). The open bars in figure 1 show the proportions of depressive symptoms in nonveterans after we adjusted for preservice differences. The veterans continued to exceed the nonveterans on most of the symp-

toms, but the differences were less striking. Differences in the frequency of the depressive syndrome were no longer significant.

Among men who met our criteria for a depressive syndrome, the severity of the disorder was similar for veterans and controls. Some symptoms were reported more frequently by the veterans, but most were reported more frequently by the nonveterans. A slightly higher proportion of the veterans reported four or more clustered symptoms (70% versus 66% for the weighted nonveterans), but more of the nonveterans saw a physician for depression.

The depressive syndrome, as we have defined it, was not a trivial problem. About one-third of both the depressed veterans and nonveterans had thoughts of death or self-harm. Almost half of each group reported anorexia, with an 8-pound weight loss, and about 60% had guilt feelings. About one-quarter of each group had to take time off from their regular activities because of depressive symptoms.

We also examined the relationship between the veterans' combat experience in Viet Nam and depressive syndromes 2 to 3 years after their return. Among the 494 nonwounded veterans whom we interviewed, 14% reported the occurrence of a depressive syndrome at some time during the 2-year follow-up period. Dividing the sample into combatants and noncombatants, we obtained proportions of 18% and 10%, respectively. This difference is significant ($p<.02$). In addition, there was a direct relationship between the number of combat events and the proportion of veterans reporting subsequent depressive syndromes.

An association of this type does not prove a causal relationship. There may be other pre-Viet Nam characteristics that predict both combat assignment and later depression which lead to a false impression that combat causes depression. In our previous study, we found a number of preservice variables that did indeed predict both combat assignment and depression, but we controlled individually for these and found that combat experience continued to predict a depressive syndrome in the first 8 to 12 months after return (1).

In this second follow-up, we found four preservice variables that predicted both combat assignment and depression: antisocial behavior, education, parental psychiatric care, and parental arrest. When we controlled for any one of these preservice variables, the relationship between Viet Nam combat experience and subsequent depression was no longer significant. Preservice antisocial behavior, for example, was quantified with a 10-point scale. We assigned up to 2 points for deviance in each of five areas: truancy, school dropout, drunkenness at a young age, fighting that led to trouble with authorities, and arrests. We then controlled for early antisocial behavior by examining the relationship between combat assignment and depression at various levels of preservice sociopathy. In every subgroup, with the exception of the least antisocial men, combatants reported more subsequent depression than did noncombatants, but this difference was not significant. The same was true for preservice education. At all levels of education, combatants reported a nonsignificant increase in subsequent depressive syndromes.

To see whether the apparent reduction in the importance of combat assignment as a predictor of later depression at the second follow-up was a function of time or an artifact of our change in sample, definitions, and analysis, we compared the predictive value of combat in the first and second follow-up periods. We used identical definitions of combat and depression, identical veterans samples (N=571 veterans), and identical methods of analysis. For both follow-up periods, we did a multivariate analysis (4) using the four preservice variables mentioned above, with depressive syndrome as defined in the first follow-up as the outcome variable. We then repeated these analyses with combat assignment added as a fifth predictor to see how much increase in explained variance there would be. In both instances, the addition of combat increased the explained variance by only a small amount, but the contribution of combat to depression was clearly greater at the first follow-up than at the second (4% versus 1%). Thus, we conclude that the development of a depressive syndrome was influenced by prior combat experiences at first follow-up but that these effects were largely dissipated by the time of the second interview.

There was little carry-over in depression from the first to the second follow-up. Only 28% of those who met our criteria for depression the first time did so the second. This represented only 2% of the entire nonwounded veteran sample. It would have been interesting to see if postcombat depressions were less persistent than those which were not combat related, but the numbers were too small for meaningful conclusions.

DISCUSSION

This investigation provides a unique opportunity to examine the effect of serving in the military and specifically the effect of the stress of combat on the long-term psychological adjustment of veterans. The sample is large and was randomly selected from men who served in Viet Nam at the height of the military campaign. Follow-up was by personal interview given by trained examiners using a structured instrument. The controls were matched for age, educational status, and other demographic characteristics. In comparing these carefully selected samples, we were unable to find much evidence of long-term depressive symptoms or syndromes that might be attributed to the military experience. It is true that the absolute proportions of veterans exceeded those of nonveterans for most of the depressive symptoms we inquired about. However, when we controlled for preservice factors that were clearly related to later psychological adjustment, these differences diminished. Preservice differences seem to play a much stronger role in psychological ad-

justment 2 to 3 years after return than do inservice variables.

We also found that combat experience played an insignificant role in the veterans' psychological adjustment 2–3 years after their return to the States. In a war like Viet Nam in which there were no "front lines" and even those stationed within major cities lived under the threat of bombardment, it is not as clear what constitutes a combat experience. It may be that combat as we have defined it is not an important predictor because it does not differentiate combatants from noncombatants in terms of the risk they were exposed to. However, the striking increase in the likelihood of being wounded or having friends killed in combat suggests that combat, as we have defined it, does identify those men particularly exposed to danger and risk during their Viet Nam experience.

Both the similarities in symptoms between veterans and nonveterans and the weak association between combat experience and depressive symptoms would suggest that the Viet Nam conflict produced few long-term psychological effects of the type we inquired about. There are no previous reports of large systematic comparisons of depressive symptoms in veterans and nonveterans. There are, however, previous studies of the relationship between combat and later depression, and the results appear to be consistent with our own. Nace and associates (5) recently reported a 2-year follow-up of over 200 veterans who had been hospitalized or were in a drug treatment center in Viet Nam. They administered the Beck Depression Inventory to their respondents and found a nonsignificant trend toward greater depression in combatants. Brill and Beebe (6), in their 5-year follow-up of World War II veterans, found that equal percentages of combatants and noncombatants were ill at the time of examination. Also consistent with our findings, they found that those with preservice personality disorders were 6 times more likely to be disabled at follow-up. Archibald and Tuddenham (7) found that stress reactions in World War II combat veterans were still present after 20 years; however, overall prevalence cannot be determined from their study, since their sample was selected from men under treatment at follow-up.

Because of differences in samples and definitions, our first and second follow-up studies are not entirely comparable. However, comparing the two as best we can, we find evidence at the first follow-up that combat was a predictor of a depressive syndrome and that this association did not disappear when preservice variables were controlled for. However, few of the men reported a depressive syndrome at both follow-up examinations. The association between combat and depression at the second follow-up was weak and did not continue to be significant after controlling for relevant preservice variables. The results of these two studies provide some evidence that combat as a stressful life event did predict depressive syndromes in Viet Nam veterans, but these depressions were short-lived, and the effect of combat as a predictor diminished over time.

Depressed Mood and Subsequent Physical Illness

BY EVELYN L. GOLDBERG, SC.D., GEORGE W. COMSTOCK, M.D., DR.P.H., AND ROBIJN K. HORNSTRA, M.D.

The authors describe the results of a matched case-control analysis in which 82 pairs of subjects were selected from a large-scale community study carried out in two general populations. Cases were those of persons hospitalized during an interval between two interviews for an illness starting during that interval or persons who died during the interval. Controls were persons with no new illnesses or hospitalizations during the interval. No relationship between measures of depressive symptomatology or depressed mood and subsequent physical illness was shown. This result corroborates the findings of prospective studies in more selected populations and suggests that it is unlikely that depressed mood is related to subsequent physical illness.

DEPRESSIVE ILLNESSES are considered to be a major public health problem (1). They are very common, but increasingly effective methods of treatment are becoming available. To increase the success of these new therapeutic modalities, it is desirable to know the natural history of the disease so that treatment may be applied at points where its effectiveness is optimal.

An important and as yet unknown aspect of the natural history of depression is whether or not depressed mood is a precursor of serious illness. This is a difficult question to answer even when the outcome studied is limited to serious physical illness. Cross-sectional and case-control studies are unlikely to yield convincing answers because of the difficulty in determining whether depressed mood preceded the illness, accompanied it, or was caused by the illness. Prospective studies can establish that symptoms of depression did precede the onset of serious physical illness more often than expected by chance, and while they cannot establish a cause-and-effect relationship because of the possibility that depressed mood may be the first symptom of a physical illness that is not yet recognizable (2–4), a failure to find an association rules out an etiological relationship.

Among the few prospective studies of this nature that have been reported, some have looked at the health of persons already diagnosed as having a depressive illness and have found that these patients do have higher rates of disease and death than the general population. Heine (5) showed a relationship between depressive illness and subsequent hypertension in a follow-up study. Excess mortality for patients with various categories of depression has been reported in seven separate studies (6–12). Suicides accounted for some of the excess, especially in the Ciompi study (10), in which most of the lower life expectancy was due to suicides.

Following psychiatric interviews of the entire adult population of two adjoining parishes in Sweden during 1947, Hagnell restudied the 2,550 subjects 10 years later (13). Each individual had originally been rated on the personality dimension of stability on the basis of responses to questions and behavior during the interview. Women classified as having substable personalities, a rubric similar to Eysenck's extravert and Kretchmer's cyclothymic types, were found to have an excess risk of subsequent cancer; this was not true for men (14).

Thomas and her coworkers have been following a group of 1,130 white males who registered in medical school between 1948 and 1964. Among those with evidence of depression at the initial examination there has been an increased risk of suicide but as yet no increased risk from other causes (15).

A larger and longer study based on data routinely collected from students on entry into university programs has been reported by Paffenbarger and coworkers (16–22). Information was available from more than 13,500 men who were admitted to the University of Pennsylvania from 1931 to 1940. Included in the initial information were a number of psychological symptoms such as palpitation, nervousness, insomnia, exhaustion, worrying, moodiness, alternating gloominess and cheerfulness, self-consciousness, and inclinations to be secretive or seclusive. On follow-up 24 to 33 years later, it was found that a sense of exhaustion on initial interview was related to subsequent death

from coronary heart disease. No association was found with the depression-related symptoms of moodiness or of alternating gloominess and cheerfulness (16). Another study (22) done 22 to 31 years later showed no association between depression-related symptoms of moodiness or cyclothymia and the incidence of peptic ulcer.

Because of the potential importance of the association of symptoms of depression and subsequent serious physical illness, the present paper reports the findings from a large prospective study expressly designed to measure the frequency of depressed mood in two distinct general populations and to assess its association with subsequent disease.

METHOD

Representative samples of dwelling units were selected in Kansas City, Mo., and Washington County, Md. Cluster sampling was used in Kansas City and systematic sampling from a geographically arrayed list in Washington County. A study subject was then randomly selected from persons over the age of 18 in each selected dwelling unit. In both communities, the sampling procedures were designed to yield successive monthly samples of adults who were representative of all community adults except for stratification by the number of adults in the household.

Interviews were conducted similarly in each community. The initial interviews were carried out between October 1971 and January 1973 in Kansas City and between December 1971 and July 1973 in Washington County. The response rates were 72% and 80%, respectively.

The initial interview schedule contained, in addition to demographic and general health questions, a number of scales designed to measure depression, happiness, and satisfaction with life. Symptoms of depression were assessed by the Center for Epidemiologic Studies Depression Scale (CES-D) (23) and depressed mood by the Lubin Depression Adjective Check List (DACL) (24, 25). Overall happiness was measured by scales developed by Bradburn (26, 27) and Gurin (28). The Cantril Ladder (29) provided an evaluation of the subjects' overall perceptions of their current life situations. In all instances, higher scores reflect more symptoms of depression, less happiness, or less satisfaction with present life situations. Cutting points were selected so that, in general populations, persons in the group with scores greater than the cutting point represent approximately 20% of the total.

The CES-D used 20 questions selected from five other depression questionnaires for their ability to discriminate between depressed and nondepressed persons (30). Duration of symptoms during the last week was rated on a scale from 0 through 3, yielding scores from 0 to 60. Cutting the scale between 15 and 16 has been shown to differentiate between depressed and nondepressed persons with considerable accuracy (31–33). The Lubin DACL is also designed to measure depressed mood. Results correlate well with those from the CES-D (31).

The Gurin Global Happiness Scale is derived from a single question relating to the subject's present happiness (28), while the Bradburn Happiness Week Balanced Scale uses several questions to assess the subject's mood (26, 27).

In using the Cantril Ladder, Present (29), the interviewer asks which rung of the "ladder of life" seems most appropriate to the subject's present condition—at the top (the best possible life), at the bottom (the worst possible life), or at some intermediate point on the scale from 0 (worst) to 10 (best). To keep the direction of the scale consistent with the others, these values were reversed by subtracting the value given by the subject from 10.

Reinterviews were restricted to a sample of the initial respondents. In Kansas City, the sample consisted of persons originally interviewed between July 1972 and December 1972; all were reinterviewed approximately 12 months after the initial survey. In Washington County, reinterviews took place between August 1973 and April 1974; the subjects were persons whose initial interviews had occurred 6 or 12 months earlier. There were 343 respondents to reinterviews in Kansas City and 660 in Washington County, representing response rates of 78% and 79%, respectively. A major purpose of the reinterviews was to ascertain illnesses that had occurred during the period since the initial interview. The portion of the questionnaire designed to elicit this information was patterned after questionnaires used in the health interview surveys conducted by the National Center for Health Statistics (34). Several different approaches were used to assure that illnesses were not forgotten or overlooked.

The subjects for the present analysis were Caucasians who completed interviews at both times and who responded to the initial interview but who died within the study areas during the study period. Nonwhites were excluded because of their small numbers in the final sample.

To expedite the analysis, a case-control approach was chosen even though the study was prospective in nature. Cases were the 66 subjects who had been hospitalized for an illness that started during the interval and the 16 who had died in the period between interviews, a total of 82 cases.[1] Controls were study subjects without new illnesses, hospitalization, or death between interviews. Each control was individually matched to a case by location, length of follow-up interval, sex, age (plus or minus five years), education, income, and employment status.

The findings were examined by matched-pairs anal-

[1]Results reported in an earlier paper (35) were based on data from 83 matched pairs. One of the original 83 matched pairs was eliminated from the present analysis because of a previous coding error; the omission of this pair made only trivial differences in the results found.

TABLE 1
Comparison of 82 Case-Control Pairs by Matching Variables

Characteristic	Cases (percent)	Controls (percent)
Location		
Washington County	56.1	56.1
Kansas City	43.9	43.9
Follow-up interval		
6 months	6.1	6.1
12 months	93.9	93.9
Sex		
Female	65.9	65.9
Male	34.1	34.1
Age		
18–44	39.0	41.4
45–64	34.1	29.3
65 and over	26.8	29.3
Educational status		
College degree	12.2	7.3
1–3 years college	17.1	15.9
High school degree	21.9	32.9
7–11 grades	36.6	35.4
0–6 grades	12.2	8.5
Employment status		
Working	47.6	50.0
Housewife	23.2	24.4

ysis, using McNemar's test to assess statistical significance (36). Median scores for each of the five scales were also looked at for cases and controls.

RESULTS

The final study group was composed of 82 matched pairs of cases and controls, 36 from Kansas City and 46 from Washington County. Their matched characteristics are compared in table 1. All of the differences between case and control groups could easily have occurred by chance. Because this was true both within and between each community, the results from the two locations were combined.

The categories of illnesses reported to have caused death or hospitalization are shown in table 2. All subjects but one were hospitalized for physical illnesses (one case was diagnosed as neurosis). Causes of death were ascertained from death certificates. For a sample of 23 subjects in Washington County, hospital records were examined to validate the diagnoses reported at reinterview. For 20 of the 23, the patients' statements and the hospital records agreed; for 2 others, there was agreement with respect to the general nature and location of the condition. One patient claimed to have had a stroke, while the hospital record referred only to an undiagnosed kidney lesion.

DACL (11–34)	50	2	16	14	.03
Gurin Happiness (2)	68	0	9	5	.64
Bradburn Happiness (4–9)	47	5	16	14	.03
Cantril Ladder, Present (5–10)[c]	47	3	17	12	.55

[a]Numbers in parentheses represent "abnormal" values.
[b]Using McNemar's chi square (36).
[c]Analysis performed on only 79 pairs because of missing data for 1 member of each of 3 pairs.

Results of the matched-pair analyses for the five scales of interest are shown in table 3, along with scores on these scales considered "abnormal." In no instance is there any indication that symptoms of depression or feelings of unhappiness were associated with subsequent serious physical illness or death. Although more cases than controls assessed their present life situation as unsatisfactory, this difference was well within chance limits.

Median scores for each of the five scales are shown separately for cases and controls in table 4. There is little indication that the cases were more depressed prior to their illnesses than the controls. The very slight differences in median scores are consistent with the fact that controls were slightly better off with respect to education and income, both of which are negatively associated with depressed feelings (37).

TABLE 4
Median Scores on Five Depression-Related Scales for Cases and Controls

Scale[a]	Cases	Controls
CES-D (0-60)	7.2	5.8
DACL (0-34)	7.1	7.6

Bradburn Happiness (0-9)	2.3	1.8
Cantril Ladder, Present (0-10)	2.7	2.0

[a]Numbers in parentheses represent range of possible scores.

DISCUSSION

This study, using comparisons of cases and matched controls with prospectively gathered data, failed to show a relationship between physical illness and depressed mood measured in various ways prior to the onset of illness. The cases—persons who died or persons with a physical illness requiring hospitalization—had no more symptoms of depression or depressed mood before becoming sick than the controls who remained well. Measures of overall happiness and present satisfaction with life, both of which are correlates of depression, also failed to show significant differences between the two groups.

Because the illness was not present (or at least not known) at the time of the initial interview, there is little question that the history of depression-related findings was obtained prior to the onset of physical illness. Of course, if disease had been present but still unapparent at the initial interview, it might have affected the level of depression of the cases. Given the wide variety of illnesses, however, it seems unlikely that this could have happened often enough to be important. Because the disease was not known at the time of the initial interview, the depression scores could not have resulted from reactions to the diagnosis of an illness.

Physical illness and death are both commonly found to be more frequent among low socioeconomic groups (38-41). A similar association is also found for depression (37, 42-45). It is not surprising, therefore, that studies which did not make allowances for this common link found mortality to be increased among depressed persons (6, 7, 9, 10). Prospective studies such as those by Paffenbarger and associates (16, 22) and by Thomas (15) in effect adjusted for socioeconomic status by the fact that their study populations were white males who had attended private universities. Neither of these two studies found evidence of an association of depression-related symptoms with subsequent illness or death, except for deaths due to suicide.

In addition to controlling for a considerable number of demographic and socioeconomic characteristics, the present study also has the advantage of being replicated in two independent general populations, each with a broad range of demographic, socioeconomic, and personal characteristics. Its findings over the short term in these broad-based populations agree with the results of long-term observations by Paffenbarger and associates (16, 22) and Thomas (15) in more restricted populations. This agreement makes it appear unlikely that depressed mood is related in a causal way to subsequent physical illness.

Depression: New Evidence in Support of Biological Differentiation

BY PAUL E. GARFINKEL, M.D., JERRY J. WARSH, M.D., PH.D., AND HARVEY C. STANCER, PH.D., M.D.

The authors studied monoamine metabolism in patients with bipolar (manic-depressive) and unipolar depressive illness and in normal control subjects under strict dietary conditions before and during administration of carbidopa, a peripheral decarboxylase inhibitor. They found that unipolar depressed patients excreted higher amounts of 3-methoxy-4-hydroxyphenylglycol (MHPG) and 5-hydroxyindoleacetic acid (5-HIAA) in the drug-free period and while receiving carbidopa and significantly less tryptamine only after carbidopa administration. Plasma tryptophan levels differed in the three groups. The authors state that their research design reveals changes in serotonin and norepinephrine metabolism in unipolar depressed subjects that distinguish this group from normal and bipolar depressed subjects, suggesting a reduced CNS uptake of tryptophan in unipolar depression.

THE DIFFERENTIATION of depressive syndromes has largely been based on clinical history. Exclusion and inclusion criteria to increase the reliability of diagnosis have also been described (1). Further, genetic studies and reports on responses to psychotropic medications have provided evidence to support the differentiation of primary depression into those conditions with a positive history of mania (bipolar, manic-depression) and those in which mania is absent (unipolar depression) (2–4). Recent reports suggested that diagnostic differentiation may be enhanced through the measurement of catecholamine metabolites (3-methoxy-4-hydroxyphenylglycol or MHPG) in urine (5–7) or serotonin (5-HT) metabolites (5-hydroxyindoleacetic acid or 5-HIAA) in cerebrospinal fluid (CSF) (8–10).

We have demonstrated the use of the selective peripheral decarboxylase inhibitor carbidopa to enhance the specificity of in vivo indexes of CNS biogenic amine function (11–13). This strategy has been used to reveal differences between unipolar and bipolar depressive patients and normal control subjects in both catecholamine and indoleamine metabolism. The biochemical profile thus obtained appears to distinguish a more homogeneous subgroup of patients with unipolar depression in which there may be a disturbance in CNS serotonin function secondary to the reduced availability of tryptophan.

METHOD

We studied 18 depressed patients (11 bipolar and 7 unipolar) with a diagnosis of primary affective disorder (1) and 10 control subjects on a clinical research ward where diet, medication, and activity were strictly controlled, as described in earlier reports (11–13). The bipolar patients were 6 men and 5 women whose mean age was 38.4 years (S.E.=3.7 years). The unipolar patients were 6 men and 1 woman; their mean age was 35.3±3.3 years. The control subjects were normal volunteers (6 men, 4 women) with no history of psychiatric disorder. Their mean age was 31.9±2.4 years. Informed consent was obtained from all of the subjects.

Following a 7-day drug-free period, each subject was studied over 10 days. This consisted of a 3-day baseline period followed by 7 days of receiving 100 mg of carbidopa three times daily. Urine was collected over 12-hour intervals (9 a.m. to 9 p.m. and 9 p.m. to 9 a.m.) for the entire 10 days for determination of 5-HIAA, MHPG, and tryptamine by methods described in earlier reports (11, 13). Free and total plasma tryptophan were determined on the first and second days of the baseline period and on the sixth and seventh days of carbidopa administration, as described in an earlier report (12). A multivariate analysis of variance was used for all 10 days and 10 nights for analysis of

FIGURE 1
Urinary 5-HIAA Excretion in Bipolar (Manic-Depressive) and Unipolar Depressed Patients and Control Subjects

MHPG and 5-HIAA data. For tryptamine, the multivariate analysis was redone using data from days 1, 2, 4, 9, and 10, including the 5-HIAA and MHPG data from these same days. Total and free plasma tryptophan were analyzed by univariate analysis of variance for days 1, 2, 9, and 10. Significant results from these analyses were followed by Duncan's Multiple Range Test for cell differences (14).

RESULTS

The results of the measurements of 5-HIAA and MHPG excretion for each of the 10 days are shown in figures 1 and 2, respectively. Unipolar depressed subjects had significantly higher MHPG ($p<.05$) and 5-HIAA ($p<.05$) excretion compared with bipolar depressed or control subjects. Carbidopa administration resulted in statistically significant decrements in MHPG ($p<.001$) and 5-HIAA ($p<.001$) excretion in all three groups of subjects. Despite the decrease, the MHPG and 5-HIAA excretion levels remained elevated in unipolar depressed subjects compared with the excretion levels in bipolar depressed and normal subjects.

No differences were found in urinary tryptamine excretion during the precarbidopa baseline period (see table 1). As previously reported (11), administration of carbidopa resulted in a profound decrease in urinary tryptamine excretion in all subjects (more than 85%, $p<.001$). However, the urinary tryptamine excretion in unipolar depressed subjects was found to be significantly lower ($p<.05$) than in bipolar depressed or normal subjects receiving carbidopa.

Free plasma tryptophan concentrations (see table 2) were not different in the three groups during the baseline period. Free plasma tryptophan was significantly elevated in unipolar depressive patients ($p<.05$) and decreased in control subjects ($p<.05$) given carbidopa. These findings were not altered by partitioning out possible correlations in total tryptophan. No significant inter- or intragroup differences in total plasma tryptophan were evident before or during carbidopa administration.

DISCUSSION

These results demonstrate a distinct profile of alterations in both indoleamine and catecholamine metabolism in unipolar depressive subjects but little change in bipolar depressed subjects. These findings were brought out only by use of a perturbation technique with a peripheral decarboxylase inhibitor.

In 1976 we reported differences in the disposition of plasma tryptophan in patients with primary depression compared with normal control subjects (12). Carbidopa produces a decrease in free plasma tryptophan in normal subjects, an effect probably mediated through reduced peripheral catecholamine metabolism and subsequent reduced lypolysis and mobilization of

unesterified free fatty acids. This inference is supported by evidence that β-adrenergic-blocking drugs prevent stress-induced increases in plasma unesterified fatty acids and subsequently free plasma tryptophan (15) but adrenaline increases these fatty acids (16). Unipolar depressed subjects display a rise rather than a decrease in free plasma tryptophan in response to carbidopa. As we suggested in 1976 (12), the differential effect of carbidopa in increasing free plasma tryptophan in unipolar depressed subjects but decreasing it in normal subjects may indicate a reduced efflux of tryptophan from the plasma compartment in unipolar depression. This reduced efflux becomes evident only after inhibition of the metabolic clearance of tryptophan through peripheral indoleamine and possibly kynurenine and transaminase pathways that may also be inhibited by carbidopa (17, 18).

The finding of reduced urinary tryptamine excretion in unipolar compared with bipolar or normal subjects supports the concept of a reduced egress of tryptophan from plasma. Tryptamine is a direct product of tryptophan decarboxylation (19). It is likely that CNS tryptamine turnover is dependent on the availability of tryptophan because of the high Km (Michaels-Menten constant) for tryptophan decarboxylation in brain and because brain tryptophan concentrations are below the saturating concentration for decarboxylation (20). Because carbidopa does not penetrate into brain and because it produces a profound inhibition of peripheral tryptamine excretion, it is likely that a large fraction of the tryptamine excreted derives from noninhibited pools of tryptamine formation such as brain. Thus reduced tryptamine excretion may reflect reduced tryptophan availability in the CNS secondary to reduced efflux or uptake from the plasma compartment.

The elevated 5-HIAA excretion in unipolar compared with bipolar depressed or normal subjects would also support this concept. Although urinary 5-HIAA excretion during carbidopa administration was significantly reduced, the gradual and progressive decrement in 5-HIAA excretion suggests that after carbidopa administration some 5-HIAA secreted in urine probably still derives from peripheral pools (13). Elevated 5-HIAA excretion may represent a peripheral compensatory route of metabolic efflux of tryptophan secondary to a reduced clearance of tryptophan from plasma through normally functioning pathways. If, in fact, the significantly reduced urinary tryptamine excretion in unipolar depressed subjects receiving carbidopa is an index of reduced brain tryptophan, this would suggest that a defect in net uptake of tryptophan is present in unipolar depression. Because of the dependence of brain 5-HT on substrate availability, such an impairment of brain tryptophan uptake could lead to reduced brain 5-HT function. Reports of reduced volume of distribution and turnover of plasma tryptophan (21, 22), lowered CSF tryptophan levels (23), and postmortem findings of reduced 5-HT and 5-HIAA in the brains of depressed subjects (24–26) support the latter hypothesis.

The elevated MHPG excretion observed in unipolar depressive patients concurs with earlier findings (5, 7). We found that MHPG excretion in bipolar depressed patients tended to be lower than in normal control subjects, but this difference did not reach statistical significance. The reduction of peripherally derived MHPG following carbidopa administration did not alter our findings. These results persisted after a separate analysis of the male subjects alone. MHPG has been reported to be reduced in bipolar depressed patients (5, 7, 13).

The increased urinary MHPG excretion in unipolar depressed patients may reflect increased CNS noradrenergic function. Furthermore, the changes in indoleamine metabolism reflect the possibility of reduced CNS 5-HT activity. These alterations may be simultaneous and independent. However, there is considerable evidence supporting a functional interaction between brain 5-HT and noradrenergic systems (27), with 5-HT and noradrenergic systems being reciprocally antagonistic (28). If such is the case, reduced CNS 5-HT function might directly or indirectly result in increased noradrenergic turnover and production of MHPG. Since a major fraction of urinary MHPG appears to derive from the CNS (29, 30), the increased urinary MHPG excretion in unipolar patients may reflect such an increased CNS noradrenergic metabolism resulting from reduced 5-HT function. The present data represent the first (to our knowledge) demonstration relating affective illness to a possible imbalance in CNS amine function. This imbalance is demonstrable in unipolar depression.

Alternatively, the MHPG findings could be due to increased adrenal catecholamine synthesis, which appears to be partly under CNS 5-HT inhibitory control (31). Reduced brain 5-HT activity could result in increased peripheral adrenergic metabolism and subsequently in increased MHPG production. It has been shown that a significant fraction of urinary MHPG may arise from peripheral epinephrine as well as norepinephrine metabolism (32).

The possibility of a reduced CNS tryptophan uptake in unipolar depressive patients may explain the inconsistencies surrounding the therapeutic efficacy of tryptophan in depression (33). An abnormality affecting the net uptake of tryptophan into brain might limit the ability of exogenously administered tryptophan to increase brain tryptophan and indoleamine metabolism. It is interesting that lithium increases brain tryptophan uptake and, initially, brain 5-HT synthesis (34). This suggests that lithium combined with tryptophan might improve the CNS uptake of tryptophan in unipolar depressed subjects, thus enhancing its antidepressant effects.

We have demonstrated changes in 5-HT and noradrenergic metabolism in unipolar depressed subjects that distinguish this group from normal and bipolar depressed subjects. These findings suggest a reduced CNS uptake of tryptophan in the pathochemistry of unipolar depression. Primary affective disorders ap-

pear to consist of a number of biochemically distinct subpopulations.

Physical Activity and Plasma Cyclic Adenosine Monophosphate Levels in Manic-Depressive Patients and Healthy Adults

BY ELEFTHERIOS LYKOURAS, M.D., EVANGELOS GARELIS, M.D., ELEFTHERIA VARSOU, M.D., AND COSTAS N. STEFANIS, M.D.

Intense exercise for one hour induced a significant increase in plasma cyclic adenosine monophosphate (cAMP) in 5 healthy volunteers. In 44 manic-depressive patients, cAMP levels correlated more strongly with mood ratings than with activity scores. The authors conclude that physical activity is one of the factors which contribute to changes of cAMP levels in affective illness.

SEVERAL GROUPS of investigators have reported that cyclic 3,5-adenosine monophosphate (cAMP) concentrations in urine are increased in mania and decreased in depression (1–4). In contrast to these reports, Cramer and associates (5) showed that depressed patients had significantly higher basal levels of cAMP in the cerebrospinal fluid (CSF) than either manic patients or controls. Others found no change in the cAMP content of urine (6, 7) or CSF (8) in affective disorders.

To our knowledge, no studies on the concentration of cAMP in the plasma of manic-depressive patients have been published. This is rather surprising, because plasma offers several advantages over urine for the investigation of the cAMP system in psychiatric patients. In contrast to urine, in which more than 50% of the concentration may be of renal origin, the plasma pool of cAMP derives from many organs, including the central nervous system (9).

Using this approach, we found that in the drug-free state plasma cAMP levels are much higher in mania and much lower in depression than normal (10).

It has been suggested (11), and denied (1, 4, 12), that changes in urinary cAMP in affective illness may simply reflect the increased or decreased psychomotor activity of such patients. The aim of the present study was to investigate the possibility that physical activity may affect plasma concentration of cAMP.

Received Nov. 9, 1977; accepted Jan. 12, 1978.

The authors are with the Department of Psychiatry, Athens University Medical School, Eginition Hospital, 74 Vasilissis Sophias Ave., Athens, Greece, where Drs. Lykouras and Varsou are Research Fellows, Dr. Garelis is Assistant Professor, and Dr. Stefanis is Professor. Address reprint requests to Dr. Lykouras.

This study was supported by grant 321/1976 from the Greek National Research Foundation.

METHOD

Four blood samples were taken from 5 healthy volunteers (3 men and 2 women) at the end of one-hour intervals, during which subjects successively engaged in usual activity, bed rest, intense exercise, and a second period of normal activity. Exercise consisted of continuously ascending and descending a staircase. The relative effect of disturbed mood and abnormal psychomotor activity on plasma cAMP in affective disorders was studied in a group of 44 unmedicated patients (28 depressed, 9 manic, and 7 normothymic). Rating of activity in these patients was based on a 9-point scale (−4 through +4). A score of zero indicated normal activity; −1 to −4, progressively decreased activity; and +1 to +4, corresponding degrees of increased activity.

A similar scale was used to rate depressed (−1 to −4), normal (0) or elevated (+1 to +4) mood. Both ratings were made at the time of blood sampling by two independent observers. For statistical analysis, the average of the two scores was used. Plasma cAMP was measured by a protein binding assay (13).

All subjects had consented to the study after being informed of its nature. All biochemical determinations were carried out blindly, i.e., on coded samples and without prior knowledge of diagnosis, ratings of activity, or other clinical information.

RESULTS

In the group of volunteers, bed rest did not affect cAMP appreciably. Conversely, exercise induced a highly significant increase ($p<.001$) in plasma concentrations (see figure 1), which returned to nearly baseline levels in 1 hour. Exercise proved to be markedly strenuous for our subjects, as shown by the approximate doubling of heart and breathing rates, which were recorded at the end of each 1-hour period (figure 1).

Results from manic and depressed patients indicate that both psychomotor activity and mood may influence cAMP levels in the plasma, as indicated by the significant correlation of each of these factors with cAMP ($r=.70$ and $r=.95$, respectively). The correlation coefficient, however, is much higher for the mood factor than for exercise (figure 2).

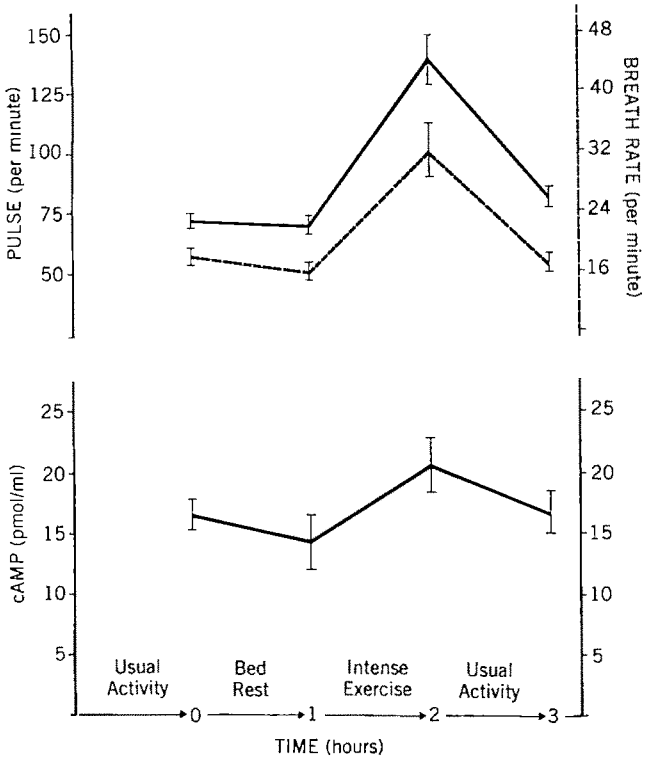
Effect of Exercise on Mean Plasma cAMP, Pulse, and Breath Rate in 5 Healthy Subjects



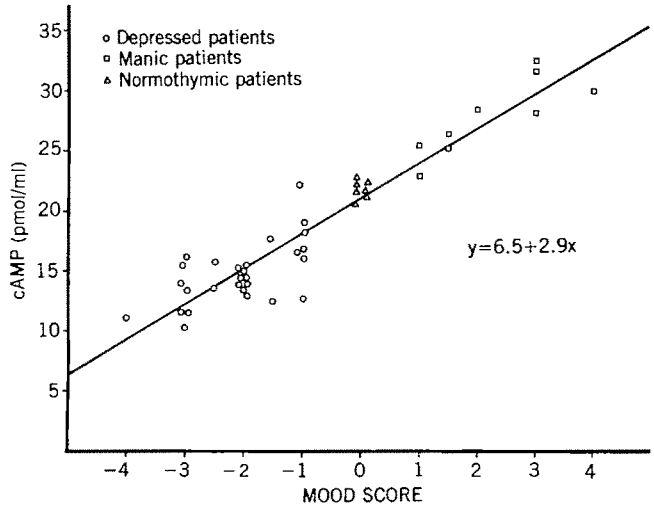


FIGURE 2
Relationship Between Plasma cAMP and Mood in Unmedicated Depressed (N=28), Manic (N=9), and Normothymic (N=7) Patients

When the 28 depressed patients were divided into subgroups on the basis of decreased, normal, or increased activity, no difference in cAMP concentrations among the 3 groups was found (table 1).

The manic (N=9) and normothymic (N=7) groups were too small to be further subdivided.

TABLE 1
Plasma cAMP Levels in Depressed Patients Showing Varying Degrees of Psychomotor Activity

Activity Level	Number of Patients	cAMP Level[a] (pmol/ml) Mean	SD
Normal	5	15.4	4.2
Decreased	17	14.4	2.1
Increased	6	16.1	2.4

[a]None of the differences is significant.

DISCUSSION

Drug-free manic-depressive patients have consistently abnormal levels of cAMP in plasma (10). Affective disturbance seems to be the primary factor associated with these changes, as suggested by the high correlation between mood and cAMP. The similar cAMP concentrations in groups of depressed patients with varying degrees of activity also point to this conclusion.

The assumption that psychomotor activity does not have a decisive influence on plasma cAMP in psychiatric patients is further strengthened by the finding of no correlation between activity and cAMP in a group of 10 drug-free chronic schizophrenics (14). These patients had normal concentrations of plasma cAMP. It is interesting in this context that in 2 patients with periodic catatonia, extreme changes in psychomotor activity (stupor or catatonic excitement) did not alter cAMP excretion in urine (15). Similarly, the high activity of hyperkinetic children does not affect urinary excretion of cAMP (16), and induced exercise did not raise cAMP concentrations in the CSF of depressed patients (5) or in the urine of healthy volunteers (4).

In contrast to the above evidence, other findings indicate that motor activity does have some effect on cAMP levels. Thus, prolonged walking leads to an increase in urinary cAMP (11). Intense exercise significantly raises concentrations of cAMP in the plasma of normal subjects, and there was a significant correlation between ratings of motor activity and cAMP concentrations in the plasma of our patients.

However, psychomotor activity and mood are generally interrelated in manic-depressive illness. Other factors, such as anxiety, may also influence cAMP concentrations in such patients. Therefore, the exact association between cAMP and affective disorders warrants more detailed exploration.

The 24-Hour Dexamethasone Suppression Test in a Clinical Setting: Relationship to Diagnosis, Symptoms, and Response to Treatment

BY WALTER ARMIN BROWN, M.D., ROBERT JOHNSTON, B.M., B.CH., M.P.H., AND DEMMIE MAYFIELD, M.D.

Of 54 male psychiatric patients undergoing dexamethasone suppression tests in a clinical setting, 40% of those with a major depressive disorder showed escape from suppression over the 24 hours after dexamethasone administration, while all of the patients with schizophrenia, neurosis, alcoholism, and drug abuse showed normal pituitary-adrenal suppression. Only 10% of the depressed patients showed resistance to suppression 8 hours after dexamethasone administration. There was no difference between depressed patients who did and did not show escape from suppression in type of previous episodes, family history, symptoms, or medication. However, those who showed escape tended to respond better to treatment and to be rated as having a more severe depression. The theoretical and clinical implications of these findings are not yet clear.

OVER THE PAST 10 years there has been considerable interest in the relationship between pituitary-adrenal activity and affective disorders. Studies involving urinary excretion of 17-hydroxycorticosteroids, urinary free cortisol, and plasma cortisol concentration show increased cortisol secretion in some depressed patients (1, 2). While it was initially thought that this hypersecretion of cortisol might be related to the turmoil or agitation accompanying depression, careful clinical assessment has shown that the hypersecretion of cortisol cannot be accounted for by a nonspecific stress response (3). A substantial proportion of depressed patients in some studies (2, 4) have shown resistance to pituitary-adrenal suppression with dexamethasone, while other studies (2, 5) have shown normal pituitary-adrenal suppression in depressed patients. These contradictory findings have been based on the overnight dexamethasone suppression test. Carroll and associates (3) have reported that while depressed patients usually show the expected suppression of early morning plasma cortisol after midnight administration of dexamethasone, a substantial subgroup show escape from suppression later in the day, unlike healthy subjects and patients with other psychiatric diagnoses, who maintain suppression for 24 hours.

Studies of urinary steroid excretion, plasma cortisol concentration, and dexamethasone suppression are consistent in showing what appears to be disinhibition of the pituitary-adrenal system in some depressed patients. The theoretical and clinical implications of this phenomenon are not clear. Consistent clinical differences between depressed patients who do and do not show pituitary-adrenal disinhibition have not been identified, and the relationship between pituitary-adrenal disinhibition and response to treatment has not been studied. Some studies of serotonin and norepinephrine metabolism in depression, and particularly the intensive study of urinary 3-methoxy-4-hydroxyphenylglycol (MHPG) excretion, have suggested the existence of multiple "biological" subtypes of "endogenomorphic" depression (6). While no clear-cut clinical differences have been demonstrated between depressed patients with low and normal urinary MHPG, there are data suggesting that MHPG levels can predict response to treatment (6).

The dexamethasone suppression test (DST) may be another marker of a subtype of depressive disorder. This test is of particular interest because its procedural simplicity and lack of risk and discomfort to the patient make it feasible as a diagnostic tool. The present study is an attempt to replicate the work of Carroll and associates (3) with the 24-hour DST in a natural clinical setting. This study assesses the diagnostic sensitivity and specificity of the dexamethasone suppression test, the differences between depressed patients who

Presented in part at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received June 12, 1978; revised Oct. 2, 1978; accepted Nov. 28, 1978.

The authors are with Providence Veterans Administration Hospital, Davis Park, Providence, R.I. 02908, where Dr. Brown is Director of the Neuroendocrine Research Laboratory, Dr. Johnston is Director of the Day Hospital, and Dr. Mayfield is Chief of the Psychiatry Service. This work was carried out under Veterans Administration Research Program 1120.

The authors wish to thank the nursing staff and physicians working on Ward 3A of the Providence Veterans Administration Hospital, who made this study possible through their continued interest and cooperation. Ms. Goldwyn Harris, Ms. June Petrucci, and Mr. Bradford Williams provided expert technical assistance.

do and do not show abnormal dexamethasone responses, and the role of psychological arousal in responses to dexamethasone.

METHOD

In August 1977 the DST was made available as a laboratory procedure to the four psychiatrists working on an inpatient psychiatric unit of a university-affiliated Veterans Administration hospital. These psychiatrists were aware of the possible usefulness of the DST in identifying patients with a depressive disorder and were encouraged to request it for all patients with clear depressive symptoms and for other patients at their discretion. These clinicians requested the DST for almost all of the patients who presented with a major depressive disorder. Patients taking phenytoin or barbiturates were excluded because of the known effects of these drugs on dexamethasone metabolism (7, 8).

The patients received 2 mg of dexamethasone orally at midnight after a blood sample (10 cc) had been drawn by venipuncture. Subsequent blood samples were drawn at 8:00 a.m., 4:00 p.m., and 11:30 p.m. the next day. In 25 patients ratings of tension-anxiety and depression-withdrawal (on a scale of 1–4) were made at the time of each blood drawing. Serum was separated and frozen until assayed. Cortisol was assayed by a solid phase radioimmunoassay, with all samples from the same subject measured in duplicate in the same assay. The interassay coefficient of variation for this method in our laboratory is 7.5% and the intraassay coefficient of variation, 6%.

A conservative criterion for normal pituitary-adrenal suppression after administration of 2 mg of dexamethasone is a reduction in serum cortisol concentration to less than 6 μg/100 ml over the 24 hours following dexamethasone administration (3, 9). We used this criterion to identify patients who did and did not show normal pituitary-adrenal suppression.

Two Board-certified psychiatrists independently diagnosed each patient who underwent a DST using Research Diagnostic Criteria (10) and assessed response to treatment (none, poor, fair, good) four weeks after admission on the basis of hospital records. These psychiatrists were not involved in the care of the patients and did not know the results of the DST. In cases in which there was disagreement on diagnosis, the final diagnosis was arrived at by consensus after reevaluation and discussion. Patients who received a diagnosis of major depressive disorder underwent further scrutiny to determine the presence or absence of previous episodes of depression, mania, or other psychiatric illness. In addition, patients with a diagnosis of major depressive disorder were independently assigned to a severe or not severe category by the two psychiatrist raters. The admitting clinician noted the presence or absence of specific psychiatric symptoms on a standard form, and these data relating to specific symptoms were obtained from the patients' charts.

RESULTS

Patients and Diagnoses

Between August 1977 and April 1978 DSTs were carried out on 54 (24%) of the patients admitted to the psychiatric unit. They were all men and ranged in ages from 21 to 82, with a mean age of 47. With rare exceptions, patients were taking one or more psychotropic drugs at the time of the DST, including tricyclic antidepressants, benzodiazepines, and neuroleptics. Five patients had one or more major physical illnesses at the time of the DST, including cardiac failure, unstable diabetes, pulmonary disease with fever, and brain tumor. The remaining 49 patients were free of acute or major physical illness and, with rare exceptions, were taking no medication other than psychotropic drugs.

The raters agreed on the diagnosis in 86% of the cases; the remaining diagnoses were arrived at by consensus after discussion. Twenty-two patients were given a diagnosis of a major depressive disorder (endogenomorphic depression); 9, schizophrenia; 10, neuroses (mixed); 11, alcoholism; and 2, drug abuse. None of the depressed patients were bipolar (history of mania or hypomania), but 14 had had previous episodes of depression. In 89% of the cases there was agreement between the raters' diagnosis using Research Diagnostic Criteria and the diagnosis of the treating physician using *DSM-II* guidelines (11).

Dexamethasone Suppression

Forty-one patients showed clear-cut pituitary-adrenal suppression with dexamethasone (table 1). In these patients all of the samples taken after dexamethasone administration had cortisol concentrations of less than 5 μg/100 ml, with the great majority of patients (88%) having serum cortisol concentrations of less than 4 μg/100 ml in all samples. Thirteen patients had serum cortisol concentration of 6 or more μg/100 ml in one or more of the postdexamethasone samples with all but one of these nonsuppressors having at least one cortisol concentration of more than 8.0 μg/100 ml. Thus there was ready differentiation of suppressors and nonsuppressors (see table 1).

Four of the 13 nonsuppressors were excluded from further data analyses because they had major physical illnesses that have been associated with pituitary-adrenal activation and, in some instances, resistance to dexamethasone suppression (3, 12, 13). Of these 4 patients, 1 had a diagnosis of depression and brittle, insulin-dependent diabetes; 2 patients, one with a diagnosis of alcoholism and the other with neurosis, had multiple medical problems including cardiac failure; and 1 had a diagnosis of schizophrenia and multiple medical problems including pulmonary disease with fever. One patient with a diagnosis of depression was found in the course of his hospitalization to have a glioblastoma. He was also excluded from further data analyses because of the possible effects of this lesion on pituitary-adrenal activity.

11:30 p.m.	16.1	5.3	9.9	2.4

The 8 nonsuppressors without evidence of major physical illness all had a diagnosis of major depressive disorder. Thus 40% of the physically healthy depressed patients in our sample had a relative lack of suppression after dexamethasone administration, while none of those with schizophrenia, neurosis, alcoholism, or drug abuse showed a lack of suppression (see table 2).

The pattern of serum cortisol response to dexamethasone in these depressed patients is particularly noteworthy. Of the 8 depressed patients who were nonsuppressors, only 2 showed resistance to suppression (serum cortisol concentrations of 6 or more μg/100 ml) at 8:00 a.m., 5 at 4:00 p.m., and all 8 by 11:30 p.m. (table 3). This pattern of response suggests initial suppression after dexamethasone administration followed by escape from suppression later in the 24-hour period. Only 10% of the depressed patients showed resistance to suppression in the 8:00 a.m. sample, while 40% of them showed escape from suppression in the 11:30 p.m. sample. Thus the serum cortisol concentration 24 hours after dexamethasone administration was the most sensitive indicator of the presence of a depressive disorder and as specific as the cortisol concentration at any other sampling point or combination of sampling points. This pattern of gradual escape from suppression in the depressed patients is in contrast to the pattern of cortisol response in the 5 patients with major physical illness (table 3). These patients tended to show high cortisol concentrations throughout the 24 hours after dexamethasone administration rather than the gradually increasing cortisol concentrations seen in the depressed patients.

Midnight Cortisol Concentrations

The period of minimal cortisol secretion lies between the late afternoon and early morning hours. While the available normative data indicate considerable variation in midnight serum cortisol concentration, a reasonable upper limit for normal serum cortisol concentration at midnight is 6 μg/100 ml (3). Using this criterion, 23 of the 49 patients (excluding those with major physical illness) had elevated midnight cortisol concentrations (6.3–30 μg/100 ml) before dexamethasone administration. All of the patients who showed escape from suppression with dexamethasone had elevated midnight cortisol concentrations (more than 6 μg/100 ml). Sixty percent of the patients with diagnoses of major depressive disorder had elevated predexamethasone midnight cortisol concentrations, while 38% of the patients with other diagnoses had elevated predexamethasone midnight cortisol concentrations. Thus midnight cortisol concentration appears to be a reasonably sensitive indicator of depressive illness but does not reliably discriminate depressed patients from those with other diagnoses.

Psychological State and Serum Cortisol Concentrations

Since the pituitary-adrenal system is so clearly responsive to transient increases in psychological arousal, we attempted to assess the degree of tension-anxiety and depression-withdrawal at the time of each blood sampling. Ratings were made on each of these variables on a scale of 1 to 4 (1=none, 2=mild, 3=moderate, 4=severe) in 25 patients. The raters included a medical technologist, psychiatric residents, and psychology interns. Psychological state ratings were made at each blood sampling point without knowledge of the previous rating.

There was a high degree of consistency among the ratings for each patient over the 24-hour period, with most patients receiving ratings of none to mild or moderate to severe for each variable over the 24-hour period. Within this sample of patients, cortisol concentration ranged from 1.0 to 18.2 μg/100 ml and psychological state ratings covered the range of the scale. There

was no relationship between predexamethasone cortisol concentration or postdexamethasone cortisol concentration and ratings of psychological state at the time of blood sampling.

Depressed Patients With and Without Escape from Suppression

Since the above analyses indicated that escape from suppression was selectively associated with depressive illness, we addressed the question of whether or not there were clinical differences between the depressed patients who did (N=8) and did not (N=12) show escape from suppression. These 2 groups did not differ significantly in mean age and weight. Six of the nonsuppressors and 8 of the 12 suppressors were taking tricyclic antidepressants at the time of the DST. The rest of the patients in each group were either taking no medication or were on neuroleptics or lithium. None of the depressed patients had a history of mania, but 6 of the nonsuppressors and 8 of the suppressors had had previous episodes of depressive illness. Thus the majority of the patients in each group had unipolar depression. A minority of the patients in each group reported a family history of psychiatric disorder.

In an attempt to evaluate the presence or absence of specific symptoms we used data that the admitting physician entered on a standard form. Most of the patients in each group were noted to have sleep disturbance, fatigue, anorexia, social withdrawal, and feelings of anxiety and depression. About 50% of the patients in each group were noted to have crying spells and suicidal ideation. Two patients who showed normal suppression and 1 who showed escape were noted to have delusions. Thus these 2 groups of depressed patients could not be differentiated on the basis of specific depressive symptoms.

There was agreement on the degree of global severity (severe versus not severe) for 87% of the depressed patients. The few cases in which there was initial disagreement were categorized by consensus after discussion. Fifty percent of the patients who showed escape from suppression were categorized as having a severe depression, compared with only 11% of those who showed normal suppression. All but 2 of the depressed patients were treated with tricyclic antidepressants. Independent global assessments of response to treatment (none, poor, fair, good) showed complete agreement for 50% of the depressed patients and approximate agreement (none-poor versus fair-good) for 88%. Fifty-seven percent of the patients who showed escape from suppression had a fair to good response to treatment compared with 20% of those who showed normal suppression.

DISCUSSION

These data are consistent with those reported by Carroll and associates (3). Like these investigators, we found that 40% of our depressed patients showed escape from dexamethasone suppression, that there was gradual escape over the 24 hours after dexamethasone administration, that the 11:30 p.m. postdexamethasone sample was the single most sensitive and specific indicator of depressive disorder, and that patients with other diagnoses showed normal suppression. We also found, as did Carroll and associates (3), that predexamethasone midnight cortisol concentration was elevated in patients who showed escape from dexamethasone suppression but that this measure of pituitary-adrenal activity did not reliably differentiate depressed from nondepressed patients. The consistency of our findings with those of Carroll and associates is particularly noteworthy in view of the fact that our study was carried out in a different clinical setting with a different patient population and used a different, albeit comparable, methodology for serum cortisol assay.

While our study certainly provides further evidence that escape from suppression after dexamethasone administration in the absence of physical illness is selectively associated with depressive disorder, several cautionary notes must be sounded. While the general classes of psychotropic drugs taken by our patients have been shown to have no effect on circadian patterns of pituitary-adrenal activity (14), these drugs have not been systematically studied for their effects on dexamethasone metabolism and pituitary-adrenal response to dexamethasone. The fact that the depressed patients who showed escape from suppression were taking the same drugs (tricyclic antidepressants) as those who did not show escape would certainly suggest that these drugs in themselves do not account for the abnormal responses to dexamethasone. Carroll and associates' data (2, 3) also indicated that tricyclic antidepressants do not affect the dexamethasone suppression test independently of their effect on clinical state. In addition, approximately half of Carroll and associates' subjects were drug-free, and in these patients escape from suppression was also selectively associated with depressive illness. In spite of these indications that psychotropic drugs are unlikely to account for the selective association between depressive illness and dexamethasone response, systematic study of this issue is important, particularly in light of the potential usefulness of the DST as a diagnostic tool.

Another issue that must be addressed is whether the different responses to dexamethasone could be due to differences in the absorption or metabolism of dexamethasone. While we have no data to definitively rule in or rule out this possibility, the fact that all of the patients who showed escape from suppression also had elevated predexamethasone midnight cortisol suggests that their response to dexamethasone represents a difference in the pituitary-adrenal system rather than aberrant disposition of dexamethasone. Parenteral administration of dexamethasone would help to clarify this issue.

Our data also point to the importance of attending to concurrent physical illness in interpreting responses to

dexamethasone. A number of specific physical illnesses other than Cushing's disease have been shown to be associated with resistance to suppression (3, 13). These data, along with ours, underscore the importance of assessing physical status in using the DST for research or clinical purposes.

The observation that escape from dexamethasone suppression occurs selectively in a subgroup of depressed patients has now been made by two groups of investigators. The clinical and pathophysiological implications of this observation are not yet clear. Using some rather gross and indirect estimates of symptom presentation, we were unable to differentiate the depressed patients who did and did not show escape from suppression with respect to specific depressive symptoms. Although our finding of no differences in symptom pattern between these groups is consistent with the findings of previous studies (4, 15), we feel that the definitive answer on this issue has not yet been reached. Continued detailed clinical assessment with particular attention to sleep patterns, diurnal variation, and other core depressive symptoms is in order.

Our data suggesting that escape from suppression may be related in part to the severity of depression is consistent with the findings of Stokes and associates (4) and Carroll and associates (16), who reported an association between ratings of severity of depression and resistance to suppression using the overnight DST. In a later study, however, Carroll and associates (15) found no relationship between severity of depression and resistance to dexamethasone suppression. These data in the aggregate suggest that global severity of depression alone does not account for the differential responses to dexamethasone among depressed patients.

Our data showed a trend for an association between a good response to tricyclic treatment and escape from suppression. Because several tricyclics were used, we were not able to systematically assess the relationship between response to a specific tricyclic and dexamethasone suppression response. The data suggesting that escape from suppression predicts a good response to treatment must be viewed in light of the tendency for the "escape" patients to have a different depressive baseline (more severe) than those who showed normal suppression. While this difference in baseline severity might account for their apparently greater improvement, our findings point to treatment response as a variable worthy of continued study.

Recent data suggesting the existence of norepinephrine- and serotonin-deficient subtypes of depression have been shown to have important treatment implications (6, 17, 18). Concomitant assessment of pituitary-adrenal activity and neurotransmitter metabolites in depressed patients would provide an important increment in our understanding of the role of these undoubtedly interrelated neurophysiological phenomena in depressive illness.

The possibility that the dexamethasone suppression test is a marker of a clinically important subtype of depression merits continued exploration. Because of its procedural simplicity and the apparent lack of interference by psychotropic drugs, the DST could be uniquely useful as a laboratory aid in the diagnosis and treatment of depression.

Facial Muscle Electromyography in Depressed and Nondepressed Hospitalized Subjects: A Partial Replication

BY DONALD OLIVEAU, M.D., AND RAGON WILLMUTH, M.D.

Imagining happy events, sad events, and the events of a typical day led to measurable electromyographic (EMG) changes in the corrugator muscle of the face in both depressed and nondepressed subjects. The depressed and nondepressed subjects could not be differentiated on the basis of muscle activity, whether depression was defined by a self-rating scale, an adjective checklist, or research criteria. Previous investigators have observed differences in the facial EMG patterns of depressed and nondepressed subjects who were not hospitalized; the authors suggest that such changes are a consequence of a general psychological stress state rather than of depression specifically.

RECENT REPORTS by Schwartz and associates (1, 2) suggest that a noninvasive electromyographic (EMG) technique may be useful in distinguishing between depressed and nondepressed mood states. These authors found that EMG patterns recorded from facial muscles while subjects imagined a variety of affect-laden events (happiness, sadness, anger, the events of a typical day) could be reliably differentiated and that depressed subjects responded differently than nondepressed subjects. Such a technique would not only provide an objective measure of depression but would be a potential means of assessing clinical progress and the effectiveness of different treatments. Schwartz and associates recruited their subjects from clinic patients considered appropriate for a trial of antidepressant medication and from volunteers who responded to a newspaper ad. We were interested in determining whether their observations could be replicated in hospitalized subjects.

Received Oct. 27, 1977; revised March 3, 1978 and July 10, 1978; accepted Aug. 10, 1978.

When this work was done, Dr. Oliveau was Clinical Assistant Professor, Department of Psychiatry, University of Vermont College of Medicine, Burlington, Vt., where Dr. Willmuth is Associate Professor. Dr. Oliveau is now Chief of Professional Education, Metropolitan State Hospital, Los Angeles, Calif. 90007.

The authors thank A. Paladino, M.D., for assistance in carrying out this study.

METHOD

We measured the EMG of the corrugator muscle and aside from minor technical and procedural differences (description available on request), the major difference between our investigation and the investigations of Schwartz and associates was the choice of subjects. Each of our subjects was hospitalized on an inpatient psychiatric unit of a general hospital. Patients were asked to participate in the experiment only if they suffered from neither psychosis nor organic brain syndrome. The experiment was explained to subjects and written informed consent was obtained. All patients who agreed to participate in the experiment were interviewed to determine whether they met research criteria for depression (3). The patients who did not meet research criteria for depression (the nondepressed group) suffered from a variety of psychiatric problems severe enough to require hospitalization. Each participant was asked to complete the Zung Self-Rating Depression Scale (SDS) (4) and a depression adjective checklist (DACL) (5) on the day when the electromyogram was taken. There were 40 subjects (21 women and 19 men) participating in the experiment.

The single pair of electrodes was placed over the right corrugator region just above the medial aspect of the eyebrow. The outline of the procedure was reviewed with each subject and a five-minute baseline recording was made during which subjects were asked to rest and "not think about anything in particular." Subjects were then asked to recall and "picture in their mind" as vividly as they could some sad event, some happy event, or the events of a typical day in their life. After each three-minute period of recollection, the subjects were asked to relax for two minutes. The subject's experience during imagery states was either sad event-typical day-happy event or happy event-typical day-sad event, and each order was used with half of the subjects in both the depressed and nondepressed groups.

The integrated EMG activity during the baseline period was compared to the activity during each of the imagery periods by reducing each to the average number of millimeters per three minutes recorded on the integrator.

[a]Values (p) are based on either changes from baseline or comparisons between imagery conditions for the total sample (N=40) and for the depressed (N=20) and nondepressed (N=20) groups separately and in comparison.

RESULTS

Table 1 shows the median changes from baseline of corrugator EMG activity during imagery conditions. Table 2 is a summary of the several comparisons between the various baseline and imagery states and between depressed and nondepressed subjects. The p values are derived from Wilcoxon matched-pairs signed-ranks tests for comparisons of the imagery states with baseline measures and from Mann-Whitney U tests for comparisons between groups of subjects (6) (all tests were two-tailed). The corresponding p values from Schwartz and associates (1) are also given.

The SDS mean scores for the depressed group and nondepressed groups were 59.8 and 38.7, respectively, which correspond closely to the means reported by Schwartz and associates (1) (58 and 37, respectively). This correspondence suggests that, at least in terms of depression, our subjects were similar to those tested by Schwartz and associates (1). The DACL mean scores for the depressed and nondepressed groups were 17.4 and 5.5, respectively.

The grouping of subjects in depressed and nondepressed categories was initially done by research criteria for depression (3). Two additional groupings according to scores on the SDS and the DACL were derived by dividing subjects according to whether they scored above or below the median score on each of these scales. The SDS scale was also used by Schwartz and associates. When the subjects were regrouped according to the SDS criteria for depression, a balanced order of presentation remained equally distributed in the two groups; however, when the subjects were classified according to the DACL criteria, a disproportionate number (N=13) of subjects in the depressed group had been given the imagery states in the sad event-typical day-happy event order. Since the amount of EMG activity observed during the typical day imagery state was greater ($p<.05$, Mann-Whitney U test, two-tailed) when the sad imagery state was presented first, the data for the DACL grouping of subjects are less reliable than the research criteria or SDS groupings.

When subjects imagined happy events, we were unable to detect significant changes from baseline EMG activity. Similarly, Schwartz and associates observed no significant changes from baseline activity under happy imagery conditions for their group of depressed subjects; however, they observed significant changes in nondepressed subjects and the total group and

found a significant difference between the depressed and nondepressed groups.

When subjects were asked to imagine sad events, we found significant changes in the total group, the nondepressed groups, and in the depressed groups; Schwartz and associates found significant changes in the total group and in the depressed group but not in the nondepressed group.

With the exceptions of the nondepressed groups (defined by research criteria and the DACL), we found significant changes when subjects imagined the events of a typical day; Schwartz and associates found similar changes only in the depressed group.

We found one significant difference between the depressed and nondepressed groups (for typical day imagery, depressed versus nondepressed as defined by the DACL), but this difference may have been influenced by the lack of a balanced order of presentation of the imagery states.

DISCUSSION

In most of the comparisons our total sample of subjects resembles the group of depressed subjects reported by Schwartz and associates. All of the significant changes from baseline activity that we observed were in the direction of increased EMG activity during imagery states, whereas Schwartz and associates reported significant decreases in activity for their nondepressed group during the happy event and typical day imagery states.

Our results support the work of Schwartz and associates in that differences were found between happy and sad imagery states. However, we were unable to detect differences between the sad imagery state and the typical day imagery state.

There are several factors that may have contributed to the lack of correspondence between our results and those of Schwartz and associates (1, 2). We instructed subjects to imagine the scenes "as vividly as you can," whereas Schwartz and associates (2) asked subjects to "vividly experience," and they noted (2) that different effects are observed when subjects are asked to "feel" than when they are asked to "think." Although we think that our instructions more closely approximate the Schwartz and associates (1) "vividly experience" and "feel" conditions than their "think" condition, the differences in instruction may have subtly influenced the data. The nearly equal mean scores on the SDS between our groups of subjects and theirs suggest that the degree of depression in the two studies was similar in both the nondepressed and depressed groups.

In a study of 5 subjects, Teasdale and Bancroft (7) observed a decrease in corrugator EMG activity from baseline levels during a happy imagery condition in 2 of their subjects but either an increase or virtually no change in the other 3. Since their study was designed for somewhat different purposes than either our study or the study of Schwartz and associates, it is difficult to assess how much their findings might contribute to understanding the differences between our observations and those of Schwartz and associates (1, 2). Nevertheless, their study does suggest that the EMG response of the corrugator muscle is variable under happy imagery conditions.

While our observations parallel those of Schwartz and associates (1) quite closely when our subjects were divided according to DACL scores, these observations cannot be considered as reliable as either the research criteria or SDS grouping observations. The "spillover" effect of presenting the sad imagery condition first to a disproportionate number in one group may have influenced the typical day observations in the DACL groupings.

It is also important to note that we made EMG recordings on only one muscle, while Schwartz and associates (1, 2) made recordings from several muscles. We chose the corrugator primarily because of the bidirectional differences between sad and happy imagery conditions they reported, which suggested to us that this muscle would be the most useful one as a clinical tool. Schwartz and associates (2) suggest that the zygomatic muscle may be more responsive to the happy imagery condition and the corrugator to several imagery conditions in addition to sadness. Thus it is possible that the general stress of the conditions for which our subjects were hospitalized tended to wash out the differences attributable to depression alone.

The results of our experiment support the observations that when subjects are asked to imagine affect-laden events reliable changes in facial muscle EMG can be observed, and that different affects evoke different patterns of change. Our results do not corroborate previous reports that depressed and nondepressed subjects respond differently; this may suggest that subjects undergoing psychological stress respond similarly to one another, i.e., differences between depressed and nondepressed subjects may be a function of psychological stress rather than a specific function of depression.
